Specific Lipopolysaccharide Serotypes Induce Differential Maternal and Neonatal Inflammatory Responses in a Murine Model of Preterm Labor

Roberta Migale,* Bronwen R. Herbert,*† Yun S. Lee,* Lynne Sykes,* Simon N. Waddington,†‡ Donald Peebles,*§ Henrik Hagberg,¶** Mark R. Johnson,*† Phillip R. Bennett,*§ and David A. MacIntyre*∗

Intrauterine inflammation is recognized as a key mediator of both normal and preterm birth but is also associated with neonatal neurological injury. Lipopolysaccharide (LPS) is often used to stimulate inflammatory pathways in animal models of infection/inflammation-induced preterm labor; however, inconsistencies in maternal and neonatal responses to LPS are frequently reported. We hypothesized that LPS serotype-specific responses may account for a portion of these inconsistencies. Four different Escherichia coli LPS serotypes (O111:B4, O55:B5, O127:B8, and O128:B12) were administered to CD1 mice via intrauterine injection at gestational day 16. Although control animals delivered at term 60 ± 15 hours postinjection (p.i.), those administered with O111:B4 delivered 7 ± 2 hours p.i., O55:B5 delivered 10 ± 3 hours p.i., O127:B8 delivered 16 ± 10 hours p.i., and O128:B12 delivered 17 ± 2 hours p.i. (means ± SD). A correlation between the onset of preterm labor and myometrial activation of the inflammatory transcription factor, activator protein 1, but not NF-κB was observed. Specific LPS serotypes induced differential activation of downstream contractile and inflammatory pathways in myometrium and neonatal pup brain. Our findings demonstrate functional disparity in inflammatory pathway activation in response to differing LPS serotypes. Selective use of LPS serotypes may represent a useful tool for targeting specific inflammatory response mechanisms in these models. (Am J Pathol 2015, 185: 2390–2401; http://dx.doi.org/10.1016/j.ajpath.2015.05.015)

Preterm birth and its associated complications are now the leading cause of death among children <5 years.1 A lack of knowledge of the basic molecular mechanisms orchestrating the onset of preterm and term labor has prevented advancements being made in early diagnosis and has inhibited the design of effective treatments. Evidence from both human and animal studies indicates that activation of inflammatory pathways in gestational tissues is a shared mechanism common to both normal and preterm birth.2,3 Intrauterine inflammation is also associated with fetal brain injury, which may lead to long-term neurological disorders, such as cerebral palsy.4,5 An increasing body of evidence supports the involvement of inflammation also, in the absence of overt infection, in preterm birth.2 A key mediator of the inflammatory response in gestational tissues at the time of labor is NF-κB light chain enhancer of activated B cells (NF-κB); however, data have also implicated activator protein 1 (AP-1) and CCAAT/enhancer-binding proteins (C/EBPs) in the

regulation of inflammatory pathways associated with the onset of labor.6–9

In various animal models of preterm labor (PTL), the Gram-negative bacterial cell wall component, lipopolysaccharide (LPS), is administered systemically to mimic bacterial infection during pregnancy or locally via an intrauterine injection to reflect ascending vaginal infection and/or chorioamnionitis.10–21 Recognition of the LPS molecule by Toll-like receptors (TLRs), expressed on the surface of intrauterine cells,15,21 activates an inflammatory cascade that drives proinflammatory cytokine production and, subsequently, the release of prostaglandins, cytokines, and chemokines promoting cervical ripening, uterine activation, and contractility.14,22 Although the inflammatory response to LPS appears to be consistently achieved in mouse models of preterm birth, significant variation in the timing of preterm birth and neonatal survival outcomes is often reported, only a proportion of which can be attributed to differences in experimental design (eg, gestation age at time of injection, site of administration, animal species/strain, and LPS dose).

The LPS molecule is composed of a complex glycolipid containing a lipid A moiety (phosphorylated glucosamine disaccharide with multiple fatty acid chains), an oligosaccharide core, and an extending glycan polymer referred to as the O-antigen. The sugar composition of this polysaccharide side chain determines the serological specificity of the molecule, whereas the lipid A group typically confers toxicity.24 Previous studies in rat models of hypothermia and albumin extravasation have reported functional differences caused by LPS serotype specificity.24,25 Treatment of fever with the selective cyclooxygenase (COX)-2 inhibitor, 4-[5-(4-chlorophenyl)-3-(trifloromethyl)-1H-pyrazol-1-yl]-benzenesulfonamide (SC-58236), is effective in the initial phase of animals administered with Escherichia coli O111:B4 LPS.26,27 Moreover, different E. coli serotypes (O111:B4, O55:B5, O127:B8, or O128:B12) were immediately incised in the longitudinal direction, and pups were isolated and sacrificed by decapitation. Right and left horns of the uterus were snap frozen separately after removal of gestational membranes, placentas, and vasculature. Myometrium samples from the right uterine horns were used for mRNA and protein analyses. After decapitation, whole pup brains were isolated and snap frozen. Tissue was stored at −80°C until extraction. Before culling, pup viability was qualitatively assessed using a scoring system as follows: 3, pups displaying full body spontaneous movement when removed from the myometrium or amniotic sac; 2, pups with partial body movement (ie, lower half or full body movement when gently prodded with forceps); 1, pups exhibiting partial body movement or movement of

Materials and Methods

Murine Model of Inflammation-Induced PTL

Pregnant (E16) female dams were administered a s.c. injection of 2.5 mg/kg morphine 20 minutes before surgery. Animals were anesthetized by isoflurane, and a laparotomy was performed as previously described.9,30,31 Briefly, both uterine horns were exteriorized and the number of live fuses per horn was recorded. An intrauterine injection of 20 μg [25 μL total volume in phosphate-buffered saline (PBS)] of either E. coli LPS serotype O111:B4, O55:B5, O127:B8, or O128:B12 (Sigma Aldrich, Gillingham, UK) or sterile PBS was injected into the upper right uterine horn between the first and second sacs. Biochemical characteristics of the LPS serotypes were consistent [phenol extracted; protein content, ≤3%; solubility, 4.9 to 5.1 mg/mL; endotoxin level, ≥500,000 endotoxin units (EU)/mg]. Animals were continuously monitored after surgery remotely via an infrared closed circuit TV camera system during recovery until tissue collection or the onset of spontaneous delivery. The onset of labor was defined as delivery of the first pup.

Tissue Collection

For tissue collection, mice were anesthetized and sacrificed by cervical dislocation. A laparotomy was performed, uteri were immediately incised in the longitudinal direction, and pups were isolated and sacrificed by decapitation. Right and left horns of the uterus were snap frozen separately after removal of gestational membranes, placentas, and vasculature. Myometrium samples from the right uterine horns were used for mRNA and protein analyses. After decapitation, whole pup brains were isolated and snap frozen. Tissue was stored at −80°C until extraction. Before culling, pup viability was qualitatively assessed using a scoring system as follows: 3, pups displaying full body spontaneous movement when removed from the myometrium or amniotic sac; 2, pups with partial body movement (ie, lower half or full body movement when gently prodded with forceps); 1, pups exhibiting partial body movement or movement of
limbs only in response to forceful prodding or squeezing of a limb with forceps and 0, pups with no response when forcefully prodded or limbs squeezed.

Protein Extraction and Western Blot Analysis

Myometrial and whole pup brain protein lysates were prepared by grinding tissue under liquid nitrogen in a mortar and pestle, then homogenizing in a modified radioimmunoprecipitation assay buffer (1% Triton X-100, 1% 3-(3-cholamidopropyl)-dimethylammonionio]-1-propanesulfonate, 0.1% SDS, 1% deoxycholic acid, 50 mmol/L NaF, 1 mmol/L orthovanadate, protease inhibitor cocktail, 25 mmol/L Tris [pH 7.4], and 150 mmol/L NaCl) at a ratio of 1 mL buffer:100 mg wet weight tissue. Protein lysates were centrifuged at 13,000 × g, and protein concentration was determined via a Bradford assay (Bio-Rad, Hemel Hempstead, Hertfordshire, UK). Extracted proteins (20 μg per sample) were separated by SDS-PAGE and transferred to a polyvinylidene difluoride membrane (GE Healthcare, Little Chalfont, UK) at 100 V (constant voltage) at 4°C. Membranes were blocked with 5% skim milk in Tris-buffered saline (TBS) supplemented with 0.1% Tween 20 (TBST) for 1 hour and then incubated overnight at 4°C with primary antibodies raised against phosphorylated (p) NF-κB: p65 Ser536 (1:1000 in TBS; catalog number 3031; Cell Signaling Technology, Hitchin, Herts, UK), p-c-Jun Ser73 (1:1000 in 1% bovine serum albumin; catalog number 9164; Cell Signaling Technology, Hitchin, Herts, UK), p-c-Fos Ser32 (1:1000 in TBS; catalog number 3084; Cell Signaling Technology); COX-2 (1:2000 in TBS containing 5% milk; catalog number sc-1745; Santa Cruz Biotechnology, Dallas, TX); and IL-1β (1:1000 in TBST containing 1% milk; catalog number AF-40174; Santa Cruz Biotechnology, Dallas, TX) and incubated at room temperature for 15 minutes, then at 37°C for 50 minutes, and finally at 85°C for 10 minutes to inactivate the enzyme. Isolated cDNA was stored at −20°C.

RNA Isolation and Real-Time Quantitative RT-PCR

mRNA was isolated from ground myometrial and whole pup brain tissue using the Nucleospin miRNA kit (Macherey-Nagel, Düren, Germany) following the manufacturer’s instructions. RNA concentration and integrity were measured with a NanoDrop 1000 spectrophotometer (ThermoScientific, Waltham, MA) and an Agilent 2100 bioanalyzer (Agilent Technologies, Santa Clara, CA). cDNA synthesis was performed on 2 μg RNA using M-MLV Reverse Transcriptase (Sigma-Aldrich). RNA was incubated with 1 μL of 0.5 μg/μL Oligo(dT)23 Primers Anchored (Sigma-Aldrich) and 1 μL of 10 mmol/L dNTP mix (Sigma-Aldrich) for 10 minutes at 70°C and then transferred onto ice. Master mix (10 μL) containing 6.5 μL of nuclease-free water, 2 μL of M-MLV Reverse Transcriptase Buffer, 0.5 μL of human ribonuclease inhibitor (40,000 U/mL; Sigma-Aldrich), and 1 μL of 200 U/μL M-MLV Reverse Transcriptase was added to each RNA sample and incubated at room temperature for 15 minutes, then at 37°C for 50 minutes, and finally at 85°C for 10 minutes to inactivate the enzyme. Isolated cDNA was stored at −20°C.

For each target gene, a gene-specific primer set of 8 to 22 bp was designed using the National Center for Biotechnology Information Database (http://www.ncbi.nlm.nih.gov/tools/primer-blast, last accessed April 29, 2015) with optimal Tm of 60°C (Table 1). Both forward and reverse primers were designed to span exon-exon junctions.

Real-time quantitative RT-PCR was performed in 384-well plates in duplicate using a total volume of 10 μL containing 2.6-μL nuclease-free water, 0.1 μL ROX reference dye (Sigma-Aldrich), 0.15 μL forward primer (20 μmol/L), 0.15 μL reverse primer (20 μmol/L), 5 μL SYBR Green JumpStart Taq ReadyMix (Sigma-Aldrich), and 2 μL of cDNA. Reactions were run on an ABI 7900HT (Applied Biosystems) chelumluminescence (ECL; GE Healthcare) using the ImageQuant LAS 4000 Imager (GE Healthcare). Membranes were stripped with 0.2 mol/L NaOH for 5 minutes at room temperature, washed in TBST, and reprobed with β-actin (1:40,000; Sigma Aldrich) as a loading control. Densitometric analysis was conducted using ImageQuant TL (GE Healthcare).

Foster City, CA) as follows: 2 minutes at 94°C and 40 cycles of 15 seconds at 94°C, 60 seconds at 60°C, and 60 seconds at 72°C; the dissociation curve was 15 seconds at 95°C, 1 minute at 60°C, and 15 seconds at 95°C. Data were processed using ABI 7900HT SDS version 2.4 software and analyzed with Excel (Office 2010; Microsoft, Redmond, WA). Gene expression levels for each sample were normalized to the endogenous reference β-actin mRNA for each well (ΔCT). Relative efficiencies of gene target and endogenous control amplification were assessed using standard curves generated for each gene by 10-fold serial dilutions of the same sample run in duplicate. The comparative CT method was used to determine differences between LPS- and PBS-treated control samples. Dissociation curve analysis, confirmed by 2% agarose gel electrophoresis, was used to verify that a single gene-specific product was produced (data not shown).

Statistical Analysis

Each experiment consisted of five biological replicates, and results are presented as means ± SD unless otherwise specified. Densitometric values were normalized to β-actin before undertaking statistical analyses using GraphPad Prism 5.0 (GraphPad Software, San Diego, CA). The statistical significance between LPS- and PBS-treated control samples was assessed using a two-tailed t-test or one-way analysis of variance (with Tukey’s post hoc test) where appropriate. P < 0.05 was considered statistically significant. For linear regression, mean levels of p-c-Jun normalized to β-actin for each serotype at 6 hours after injection were calculated and regressed against mean time of delivery for each serotype. The coefficient of determination (r²) of the linear regression was calculated and reported as a measure of goodness of fit.

Results

E. coli–Derived LPS Serotypes Induce Different Maternal and Neonatal Outcomes in a Murine Model of PTL

To characterize the effects of different LPS serotypes on PTL induction and neonatal outcome in mice, pregnant dams received an upper intrauterine injection of 20 μg of E. coli–derived LPS serotype O111:B4, O55:B5, O127:B8, or O128:B12 on E16. Although control dams administered PBS delivered approximately 60 ± 15 hours postinjection (p.i.) at term, animals injected with O111:B4 delivered 7 ± 2 hours p.i., O55:B5 delivered 10 ± 3 hours p.i., O127:B8 delivered 16 ± 10 hours p.i., and O128:B12 delivered 17 ± 2 hours p.i. (data are given as means ± SD) (Figure 1A). The percentage of dams who delivered preterm with each serotype was 100%, where preterm birth was defined as delivery before 36 hours postinjection. Major differences were also observed in fetal viability at 6 hours after LPS administration (Figure 1B). Pup survival rates in dams injected with PBS or O128:B12 were 100%, with pups displaying a strong response to mechanical stimuli. However, in animals injected with LPS O111:B4, no surviving pups were observed 6 hours p.i. Pup survival rates for O55:B5 and O127:B8 serotypes were 80% and 95%, respectively, with pups displaying a reduced response to mechanical stimuli compared with PBS control or O128:B12 treated animals.

Activation of Myometrial AP-1 Is Associated with the Onset of PTL

To investigate transcription factors potentially involved in modulating inflammation preceding myometrial contractile activation in response to LPS serotype treatment, Western blot analysis was used to examine the phosphorylation status of three key inflammatory transcription factors (NF-κB, AP-1, and C/EBPβ) in myometrium samples collected from treated and control animals 6 hours after injection, before delivery (Figure 2, A and B). Administration of LPS O111:B4 led to a 3.4-fold increase in the phosphorylation of the AP-1 subunit, p-c-Jun, compared with PBS control (means ± SD, 7.9 ± 6.2 arbitrary units (AUs) and 2.3 ± 1.6 AUs, respectively; P < 0.05). Induction of p-c-Jun phosphorylation by LPS O111:B4 was 5.3-fold higher than levels achieved by LPS O127:B8 (1.5 ± 2.5 AUs, P < 0.05) and 26-fold higher than

![Figure 1](image-url)

**Figure 1** Specific *Escherichia coli* lipopolysaccharide (LPS) serotypes induce differential maternal and neonatal outcomes in a murine model of preterm labor. **A:** The mean time of delivery of control dams administered an upper intrauterine injection of phosphate-buffered saline (PBS) is 60 ± 4 hours postinjection (p.i.), whereas those administered O111:B4 deliver 7 ± 1 hours p.i., O55:B5 deliver 10 ± 1 hours p.i., O127:B8 deliver 16 ± 4 hours p.i., and O128:B12 deliver 17 ± 1 hours p.i. **B:** Pup viability rates at 6 hours postinjection are 100% for PBS and O128:B12-treated dams; however, in the case of O111:B4, all pups die at 6 hours. Pup viabilities for O55:B5 and O127:B8 serotypes are 80% and 95%, respectively. **P < 0.001 indicates significant differences compared with PBS-injected control dams; † P < 0.05 indicates significant differences within the LPS treatment group (one-way analysis of variance with Tukey’s post hoc analysis). n = 5 (A and B).
LPS O128:B12 (0.3 ± 0.1 AUs, \(P < 0.05\)). No difference in AP-1 activation was observed in animals treated with O55:B5 (3.0 ± 3.0 AUs), O127:B8, or O128:B12 compared with PBS-injected control dams (2.3 ± 1.6 AUs). Levels of activated NF-κB in control and treated animals remained largely unchanged, as assessed by detection of phosphorylated p65 (Figure 2, A and C). Although the levels of C/EBPβ activation between PBS control and LPS-treated animals also remained unchanged, significantly less phosphorylation of both the transcriptionally active C/EBPβ isoform, liver-enriched activating protein (LAP), and the functional LAP antagonist, liver-enriched inhibitory protein (LIP), was observed in the myometrium of dams treated with O127:B8 (LAP, 0.8 ± 0.5 AUs; LIP, 0.7 ± 0.3 AUs) and O128:B12 (LAP, 0.6 ± 0.1 AUs; LIP, 0.5 ± 0.1 AUs) compared with O111:B4-treated animals (LAP, 1.7 ± 0.7 AUs; LIP, 1.9 ± 1.0 AUs) (Figure 2, A and D). Linear regression analysis showed a moderate correlation \(\left( r^2 = 0.37, P < 0.001 \right) \) (Figure 2E) between p-c-Jun levels and labor onset, where higher levels of p-c-Jun are associated with rapid onset.

**E. coli** LPS Serotypes Induce Variable Expression of Proinflammatory and Procontractile Genes in Mouse Myometrium

To investigate the LPS serotype-specific effects on the acquisition of a laboring phenotype, real-time quantitative RT-PCR was used to analyze the myometrial mRNA expression of proinflammatory and procontractile genes 6 hours after intrauterine injection of vehicle control or LPS serotype-5. Compared with PBS control, an increase in mRNA of the key labor-associated genes encoding the prostaglandin synthase enzyme Cox-2 was observed after LPS O111:B4 (21.1-fold change, \(P < 0.001\)), O55:B5 (15.5-fold change, \(P < 0.001\)), O127:B8 (20.1-fold change, \(P < 0.001\)), and O128:B12 (6.8-fold change, \(P < 0.01\)) injection (Figure 3A). Furthermore, induction of Cox-2 mRNA was 3.1-fold higher in LPS O111:B4-treated animals compared with O128:B12 (\(P < 0.05\)).

Cx43 mRNA levels were increased twofold after treatment with O127:B8 (\(P < 0.01\)) compared with control animals, whereas levels in LPS O55:B5 and O128:B12 remained similar to PBS-injected control mice (Figure 3B). Injection of LPS O111:B4 induced a 1.7-fold increase in Cx43 mRNA expression. An increase in tumor necrosis factor-α (Tnf-α) mRNA levels was induced by all tested LPS serotypes, with the highest response induced by LPS O111:B4 (11.3-fold change, \(P < 0.001\)) compared with control (Figure 3C). A similar pattern of Il-1β mRNA induction was observed in response to LPS treatments; however, statistical significance was not reached (Figure 3D). Clear LPS serotype-specific activation of Il-6 mRNA was detected, with LPS O111:B4 eliciting a 52-fold increase (\(P < 0.001\)) compared with PBS control animals, whereas
O55:B5, O127:B8, and O128:B12 induced a 14-fold ($P < 0.01$), 31-fold ($P < 0.001$), and 12-fold ($P < 0.01$) increase compared with control levels (Figure 3E). Levels of Cxcl2 mRNA, the functional murine homologue of the human IL8 gene (referred to as Il-8 herein), consistently increased between 13-fold and 26-fold ($P < 0.001$) after all LPS serotype treatments compared with PBS control-treated dams (Figure 3F).

MMP mRNA levels of the extracellular matrix degradation enzymes, metalloproteinases Mmp3 and Mmp10, increased in a LPS serotype-dependent manner. Although all serotype treatments promoted Mmp3 mRNA expression compared with control levels, LPS O111:B4 (6.6-fold increase, $P < 0.001$) and O127:B8 (8.6-fold change, $P < 0.001$) led to significantly higher induction than O55:B5 (2.9-fold) or O128:B12 (3.4-fold) (Figure 3G).

Similarly, levels of Mmp10 mRNA expression significantly increased 6 hours after injection with LPS O111:B4 (5.2-fold change, $P < 0.05$) and O127:B8 (3.7-fold change, $P < 0.05$), yet no change in Mmp10 mRNA levels was observed between control and O55:B5 or O128:B12 treatments (Figure 3H). mRNA levels of inducible nitric oxide synthase (iNOS) consistently increased after treatment with LPS O111:B4 (38.2-fold change, $P < 0.001$), O55:B5 (21.5-fold change, $P < 0.001$), O127:B8 (29.8-fold change, $P < 0.001$), and O128:B12 (31.8-fold change, $P < 0.001$) (Figure 3I).

Characterization of LPS Serotype-Specific Modulation of Inflammatory and Uterine Activation Associated Proteins in the Myometrium

By using Western blot analysis, we next assessed the levels of proteins associated with uterine activation in the myometrium of animals administered the differing LPS serotypes or PBS control. To achieve this, dams on E16 were sacrificed 6 hours after intrauterine injection of PBS control or LPS serotypes O111:B4, O55:B5, O127:B8, or O128:B12, and myometrium protein lysates were analyzed for the key inflammatory mediator, IL-1β, and the uterine activation associated proteins COX-2 and CX43. Densitometric analysis of immune-reactive bands revealed significant differences in protein expression between control and LPS-treated groups.
protein revealed that levels of the IL-1β precursor, pro–IL-1β (relative molecular mass = 31,000), significantly increased by LPS O111:B4 compared with PBS-treated animals (2.0 ± 0.9 and 0.2 ± 0.1 AUs, respectively; \( P < 0.001 \)). In addition, LPS O111:B4 significantly increased the expression of pro–IL-1β compared with O55:B5 (0.8 ± 0.3 AUs, \( P < 0.05 \)), O127:B8 (1.0 ± 0.2 AUs, \( P < 0.05 \)), and O128:B12 (0.9 ± 0.4 AUs, \( P < 0.05 \)) (Figure 4, A and B). Increased cleavage (relative molecular mass = 28,000) of IL-1β compared with PBS (0.1 ± 0.0 AUs) was observed after LPS O127:B8 (2.1 ± 0.7 AUs, \( P < 0.01 \)) and O128:B12 (1.7 ± 1.0 AUs, \( P < 0.05 \)) treatments (Figure 4, A and C). In contrast to mRNA levels, protein expression of COX-2 was unchanged with LPS O111:B4 and O55:B5 compared with control (1.1 ± 0.3 AUs), but decreased levels were detected in the myometrium of those animals administered O127:B8 (0.7 ± 0.1 AUs) compared with O111:B4 (1.3 ± 0.3 AUs, \( P < 0.05 \)) or O128:B12 (0.8 ± 0.1 AUs) compared with O55:B5 (1.2 ± 0.4 AUs, \( P < 0.05 \)) (Figure 4, A and D). Levels of total CX43 remained similar in all treatment groups (Figure 4, A and E).

Characterization of AP-1 and NF-κB Activation in Neonatal Brain in Response to Upper-Uterine Injection of Differing E. coli LPS Serotypes

To investigate the potential mechanism of LPS-induced fetal death observed with specific LPS serotype treatments, the activation pattern of the proinflammatory transcription factors, AP-1, NF-κB, and CEBP/β, was assessed. Pup brains were harvested from pregnant mice 6 hours following injection of PBS control or specific LPS serotype, and Western blot analysis was used to assess phosphorylation of the AP-1 subunit, p-c-jun, the NF-κB subunit, p-p65, and the LIP and LAP isoforms of CEBP/β (Figure 5, A–C). No change in the levels of p-c-jun or p-p65 was identified in pup brain after LPS administration (Figure 5, A and B). The CEBP/β isoforms LIP and LAP were not detected in pup brain protein lysates (Figure 5A).

Effect of LPS Serotypes on Inflammatory Gene Expression in the Neonatal Brain

Evidence suggests that activation of inflammatory pathways in the neonatal brains is the primary cause of neonatal brain injury in the context of PTL.32,33 By using real-time quantitative RT-PCR, we explored the gene expression pattern of inflammatory cytokines (Il-6, Il-8, Il-1β and Tnf-β mRNA) whose exacerbated expression in neonatal brain during the gestational period has been implicated in the development of fetal inflammatory response syndrome, leading to a broad spectrum of neurodevelopmental disorders after birth.34 Additional neuronal markers for brain damage, including glial fibrillary acidic protein (Gfap mRNA) and myelin proteolipid protein (Plp mRNA), as well as inducible nitric oxide synthase (iNOS) and endothelial Nos (Nos3), were assessed. LPS O111:B4 treatment caused a significant increase in Il-8 mRNA levels in the neonatal brain compared with control (6.6-fold change, \( P < 0.01 \), and
this increase was also significantly higher compared with O128:B12 treatment (4.1-fold change, \( P < 0.01 \)) (Figure 6A).

No significant changes were detected in the levels of Il-6, Tnf-\( \alpha \), and Il-1\( \beta \) mRNA after LPS treatment (Figure 6, B–D). Maternal LPS administration did not alter expression of any of the assessed brain damage markers in the neonatal brains (Figure 6, E–H). Similar results were observed in samples collected from pups isolated 4 hours after LPS O111:B4 intrauterine injection, where only Il-1\( \beta \) was significantly increased compared with PBS (3-fold change, \( P < 0.05 \)), before any fetal demise being observed (Supplemental Figure S1). Efforts were made to assess protein levels of both full-length and cleaved IL-1\( \beta \) in pup brain protein extracts; however, immune-reactive protein was not detected (Supplemental Figure S2).

Discussion

LPS Serotype Structure, Function, and Route of Administration

In this study, we investigated the effects of four different E. coli LPS serotypes (O111:B4, O55:B5, O127:B8, and O128:B12) in a murine model of infection- and inflammation-induced PTL. Intrauterine injection was selected as the route of administration because it best mimics the most observed clinical scenario of decidua/myometrial infection, which is responsible for 25% to 40% of all preterm births.35,36 We specifically chose LPS purified from E. coli because it is the most frequently used LPS isolate in the context of infection- and inflammation-induced preterm birth models, and because colonization of the maternal vaginal flora and urinary tract by E. coli is associated with increased rate of PTL and poor pregnancy outcomes.37,38 Furthermore, E. coli is the bacteria most frequently isolated from neonates who develop sepsis or meningitis postpartum.39

Our data clearly show that, although all serotypes tested lead to PTL, latency between time of injection and onset of labor markedly varied between serotypes administered. These data suggest that subtle changes in the sugar composition of the O-antigen possess the ability to differentially activate functional pathways that precede myometrial activation and labor onset. Detection of LPS from Gram-negative bacteria, such as E. coli, is achieved primarily through its interaction with TLR4, which is expressed in the myometrium and other gestational tissues.21,40 Bäckhed et al41 have previously shown a contribution of LPS substructures to its endotoxic properties, indicating that the polysaccharide O-antigen element may interfere with lipid A recognition by the TLR4 receptor complex. Structural variances in the O-antigen may thus change the interaction of LPS molecules with the TLR4 receptor complex, possibly resulting in differential activation of downstream inflammatory pathways. Evidence for this includes the acquisition of bacterial immune evasion properties through modulation of O-antigen composition that alters macrophage recognition and phagocytosis of LPS molecules.42,43

Impact of LPS Serotype on Maternal and Fetal Outcome

Our data show the existence of a relationship between latency from LPS injection to labor onset and pup survival rates. LPS O111:B4 induced the most rapid PTL onset (7 hours p.i.) and was accompanied by 100% fetal death at 6 hours after administration. In contrast, animals injected with LPS O128:B12 delivered 17 hours p.i. with 100% pup survival. Similar rates of infection- and inflammation-induced preterm birth are achieved in mice when administered 25 \( \mu \)g per mouse LPS O111:B4 i.p. on either E16 or E17.44 Yet, in this
model, pup survival rates are reduced from 58% at E17 to 39% at E16, suggesting a correlation between gestational age and survival rate. In our study, pup survival rates were consistently assessed on E16, precisely 6 hours after LPS administration, and show that despite sharing the same gestational age, offspring were differentially susceptible to intrauterine fetal death, depending on the serotypes used to induce PTL. These data indicate that fetal death is influenced by LPS serotype and should be considered when designing studies aimed to investigate fetal outcome in the context of infection- and inflammation-induced PTL.

LPS Serotypes Differentially Activate Uterine Inflammatory Pathways

To gain a better understanding of the potential mechanisms underlying the observed maternal response to LPS serotype, we examined the activation of key inflammatory transcription factors known to regulate inflammatory and contractile pathways in the myometrium at the time of labor onset. We demonstrated that latency to labor after LPS injection correlates with the degree of AP-1 activation, but there is no activation of NF-κB or C/EBPβ. This is consistent with our recent findings showing that murine PTL induced by intrauterine injection of LPS serotype O111:B4 is characterized by AP-1 activation and does not require NF-κB activation.9 Our data, therefore, provide further evidence that AP-1 activation is a critical regulator of the terminal pathways or labor onset. However, inflammatory transcription factor activation varied greatly between LPS-serotype treatment, as did downstream activation of associated inflammatory and contraction genes and proteins. For example, LPS O111:B4 treatment led to the most rapid and potent stimulation of AP-1 and, consequently, the most robust stimulation of Tnf-α, Il-6, Il-8, and Mmp10 mRNA. Although substantially less AP-1 activation was observed in the myometrium collected from LPS O127:B8 treated animals, robust increases in mRNA levels of Tnf-α, Il-6, Il-8, and Mmp10, as well as Cx-43 and Mmp3, were detected at 6 hours p.i. These results allude to differences in transcriptional regulation of inflammatory pathway activation induced by the different LPS serotypes. These differences appear to extend to protranslational

Figure 6  Effect of different lipopolysaccharide (LPS) serotypes on inflammatory gene expression in the fetal brain tissue. Expression of the mRNA of inflammatory genes, Il-8 (A), Il-6 (B), Il-1β (C) Tnf-α (D), neutrophic factors including glial fibrillary acidic protein (Gfap E), proteolipid protein (Plp F), inducible nitric oxide synthase (iNOS; G), and endothelial Nos (Nos3; H), was assessed by real-time quantitative RT-PCR in fetal brain tissue collected 6 hours after surgery from mice injected with either phosphate-buffered saline (PBS) or LPS (serotypes O111:B4, O55:B5, O127:B8, or O128:B12). Data are presented relative to β-actin mRNA levels. n = 5 (A–H). *P < 0.05, **P < 0.01 (one-way analysis of variance with Tukey’s post hoc test).
regulation of proteins involved in contractility and inflammation. For example, although comparable levels of IL-1β mRNA were observed between LPS treatments, significant differences in the levels of pro–IL-1β and cleaved IL-1β were identified. Protein expression levels of the proinflammatory cytokine IL-1β were significantly increased by LPS O111:B4 treatment. IL-1β is synthetized as a precursor of 31 kDa that undergoes cleavage after activation of the inflammasome complex. The inflammasome activation yields the production of a 28-kDa intermediate product that is retained in the cells longer than the mature form and can be detected to infer the production and secretion of the mature IL-1β peptide (17 kDa). It is currently unclear whether these differences represent differing degrees of serotype-specific stimulation of common molecular pathways involved in myometrial contractility and inflammatory response or serotype-specific activation of unique pathways.

Production of downstream inflammatory mediators, such as IL-1β, TNF-α, and COX-2, by specific LPS serotypes could potentiate the inflammatory response via a positive feedback mechanism that could partly account for the maternal and neonatal phenotypic differences observed in this study. Although detailed characterization of the relative contribution of these mediators to inflammatory pathway activation is important, our data nevertheless show that different LPS serotypes differentially modulate TLR4-mediated inflammatory activation and provide evidence that a proportion of the reported variability in preterm birth and pup survival rates in murine models can be attributed to LPS serotype.

Impact of LPS Serotypes on Pup Survival and Neonatal Brain Inflammation

Activation of inflammation in the neonatal brain and subsequent production of inflammatory cytokines, such as IL-1β and TNF-α, are correlated with adverse neonatal outcome in premature newborns. By using an intrauterine injection of LPS to induce preterm birth in the mouse, Elovitz et al previously reported activation of type 1/type 2 helper T-cell cytokines and inflammatory markers in the fetal pup brain 6 hours after injection using a high dose of 250 μg LPS O55:B5. A low-dose intrauterine injection of 50 μg LPS O55:B5 results in a modest increase of inflammatory mRNA markers in the pup brain 7 days after delivery. The comparatively low dose of LPS used in our study to induce preterm birth may partly explain the lack of observable differences in levels of phosphorylated NF-κB and AP-1 in pup brain extracts at 6 hours after injection of 20 μg LPS O111:B4 and increase in one (Il-8 mRNA) of the eight inflammatory and brain injury markers assessed in the pup brain. It is possible that activation of inflammatory transcription factors in the pup brain occurs before the 6-hour sampling time point examined in this study. We have recently shown that myometrial activation of AP-1 after LPS O111:B4 occurs as early as 1 hour after injection. The onset of PTL 7 hours after injection of LPS O111:B4 may not be a sufficiently long enough time to permit development of a detectable inflammatory response in the fetal brain. Conversely, it is possible that pup brain inflammation may be detectable in animals treated with LPS O55:B5, O127:B8, or O128:B12 at later stages after injection. Regardless, the marked difference in fetal loss rates between LPS serotypes has important significance for studies using LPS as a model of neonatal brain inflammation and injury.

It has been proposed that intrauterine fetal death in response to LPS treatment may occur because of maternal factors that influence susceptibility to LPS and efficiency of LPS migration through the placenta to the fetus. Maternally produced inflammatory mediators may then cross the placenta to the fetus and elicit Fas-mediated apoptosis of placental cells. This may provide a potential mechanism for the increased Il-8 mRNA levels observed in the pup brain and the difference in neonatal outcomes observed in our study in the absence of any inflammatory transcription activation.

Clinical Relevance of LPS Serotype-Specific Inflammatory Responses in Preterm Birth

Our findings that E. coli–derived LPS serotypes elicit specific activation of TLR4-mediated inflammatory activation in the pregnant host and neonate may be of important clinical relevance. Bacterial serotypes represent different variations within species that are classified primarily because of surface antigen properties. Subspecies classification of bacteria on the basis of serotype has long been recognized as an important determinant of clinical outcome. For example, group B streptococci (Streptococcus agalactiae) are recognized as the leading cause of serious bacterial infections in neonates. A difference in group B streptococci virulence is associated with production of serotype-specific capsular polysaccharide, which inhibits deposition of host complement factor C3b and subsequent opsonophagocytosis. Similarly, pneumococcal isolates of serotypes 1 and 5 are associated with invasive disease, whereas serotypes 6B and 23F are associated with carriage. In identifying and characterizing major differential effects induced by four E.coli serotypes, our data provide evidence that subspecies of bacteria are likely to induce different innate immune response patterns in vivo. Such findings are important considerations for the future design of therapeutics aimed to inhibit specific bacteria-induced inflammatory pathway activation as a strategy to prevent preterm birth and associated neonatal brain damage.

Conclusion

In conclusion, we provide evidence that specific LPS serotypes induce differential activation of inflammatory transcription factors as well as downstream contractile and inflammatory pathways in both the myometrium and
neonatal pup brain. Although these data may provide important information that can account, in part, for reported differences in murine models of infection- and inflammation-induced PTL, they also indicate that the use of selective LPS serotypes may provide a useful tool for targeting and exploring specific inflammatory response mechanisms in mouse models of preterm birth.
