Keywords: fullerenes, solubility, configurational entropy, field-effect transistors, organic solar cells

Fullerenes are an intriguing class of organic semiconductors that feature a high electron affinity and exceptional charge transport properties, desirable for a number of thin-film optoelectronic applications such as field-effect transistors (FETs) and organic solar cells. Despite their desirable solid-state properties a major disadvantage of pristine C₆₀ and C₇₀ is the seemingly poor solubility in organic solvents,^[1, 2] which however can be substantially improved by attaching exohedral moieties to the fullerene cage, albeit at the expense of a high electron mobility.^[3-5] In addition, pristine fullerenes suffer from the strong tendency to crystallize during solvent removal, which complicates formation of continuous thin films. As a result, substituted fullerenes, such as in particular phenyl-C_x-butyric acid methyl esters (PCBM_s; x = 61 or 71), are by far the most widely studied electron acceptor material for organic photovoltaic applications. The trade-off between increased solubility and reduced electron mobility has so far been acceptable for thin-film solar cells because the latter is still sufficiently high to not limit solar cell performance, which more strongly depends on the precise active layer nanostructure. However, as future improvements in device efficiency rely on thick active layers and high-mobility materials,^[6] the use of pristine fullerenes may prove to be advantageous provided that solubility issues can be addressed and a favorable nanostructure can be achieved.

The most efficient active layer nanostructure of organic solar cells is the bulk-heterojunction, which is typically prepared by co-processing a fullerene acceptor and a suitable donor from a common organic solvent. Although devices based on the pristine fullerene C₇₀ have been reported for both polymer and small-molecule donors with a power-conversion efficiency PCE of 5.1 % and 5.9 %, respectively,^[7, 8] the most competitive results are currently achieved with the more soluble PCBM_s, which can yield a PCE of more than 10 %.^[9] As low cost is the major selling point of organic photovoltaics, it is desirable to choose the most cost-effective materials. In this regard, the use of PCBM_s as the electron

acceptor is not optimal. The additional synthesis steps required to prepare these derivatives from pristine fullerenes considerably increase the energy footprint, which implies a higher environmental impact as well as an overall higher materials cost. For instance, Anctil *et al.* calculated a life cycle embodied energy as low as about 8 GJ kg⁻¹ for the as-synthesized C₆₀:C₇₀ mixture, which increases to 25 GJ kg⁻¹ for C₆₀ and 38 GJ kg⁻¹ for C₇₀ after separation and electronic-grade purification.^[10] In contrast, preparation of substituted fullerenes consumes significantly more energy, i.e. 65 GJ kg⁻¹ and 90 GJ kg⁻¹ for electronic-grade PC₆₁BM and PC₇₁BM, respectively. Therefore, the use of pristine fullerenes and in particular C₆₀:C₇₀ mixtures may result in significant energy savings provided that the ability to fabricate opto-electronic devices from solution is not impaired.

Gratifyingly, previous studies have shown that the solubility of C₆₀ and C₇₀ can be strongly enhanced by co-dissolution in a common organic solvent such as styrene, *o*-xylene and *o*-dichlorobenzene (*o*-DCB).^[2, 11] In this communication we establish that the observed enhancement in solubility occurs due the high configurational entropy associated with C₆₀:C₇₀ mixtures, which in addition facilitates the formation of amorphous thin films. Moreover, we demonstrate that this ‘entropic dissolution’ of C₆₀:C₇₀ mixtures is an effective strategy that permits to prepare high-performance FETs with an electron-mobility of 1 cm² V⁻¹ s⁻¹ as well as highly reproducible polymer solar cells with a PCE of 6% and a thermally stable active layer.

In a first set of experiments we studied the solubility of C₆₀ and C₇₀ as well as 1:1 C₆₀:C₇₀ mixtures at 27 °C in a variety of organic solvents with a wide range of boiling points, including *o*-xylene, *o*-DCB, and 1-chloronaphthalene (Table 1). The solubility was determined by adding an excess of fullerene material to the various solvents, followed by dissolution of the soluble fraction over the course of two days and careful determination of the concentration after removal of the insoluble fraction by centrifugation (cf. Experimental

Section for details). For all investigated solvents we find that the solubility of the 1:1 mixture is significantly enhanced compared to the solubility of either of the pure components in the same solvent. More polar chlorinated solvents gave rise to the highest solubility, reaching 62 g L⁻¹ for the high boiling point solvent 1-chloronaphthalene. Intriguingly, we also observed a relatively high solubility of 19 g L⁻¹ for *o*-xylene, which opens up the possibility of processing pristine fullerenes from more benign, i.e. less toxic non-chlorinated solvents.

In order to elucidate the origin of the enhanced solubility of pristine fullerene mixtures we carried out a more extended study of the solubility as a function of C₆₀:C₇₀ ratio with *o*-DCB as the solvent, which is commonly used for device processing. For reference C₆₀ and C₇₀ we find a solubility of 22 g L⁻¹ and 26 g L⁻¹, respectively. In contrast, all C₆₀:C₇₀ mixtures displayed a notable increase in solubility, which reached a broad maximum at 54 g L⁻¹ for a 1:1 weight ratio (**Figure 1a**). We explain this observation by the higher configurational entropy of the ternary C₆₀:C₇₀:*o*-DCB system as compared to the reference C_x:*o*-DCB binaries (x=60 or 70). For dilute concentrations of fullerene solutes, which have a finite molecular volume, the entropy gain upon dissolving two instead of one component in a common solvent can be approximated by:

$$\Delta S \propto \phi_{C_{60}} \cdot \phi_{C_{70}}, \quad (1)$$

where $\phi_{C_{60}}$ and $\phi_{C_{70}}$ are the volume fractions of C₆₀ and C₇₀, respectively (see Supporting Information for the derivation of equation 1). According to equation 1 the highest entropy gain and thus solubility can be anticipated for a 1:1 volume ratio, i.e. $\phi_{C_{60}} = \phi_{C_{70}}$. Adams *et al.*^[12, 13] have calculated a van der Waals molecular volume V_{vdW} of 549 Å³ for C₆₀ and 646 Å³ for C₇₀. Comparison with the molar masses M of the two fullerenes suggests a close to identical molecular mass density $\rho = M/V_{vdW}$, i.e. $\rho_{C_{60}} \sim \rho_{C_{70}} \sim 1.3 \text{ g mol}^{-1} \text{ Å}^{-3}$, and therefore a 1:1 C₆₀:C₇₀ volume ratio corresponds to a 1:1 C₆₀:C₇₀ weight ratio. Strikingly, we indeed observe that the maximum solubility for the investigated ternary solutions is centered

at a 1:1 C₆₀:C₇₀ weight ratio. The ternary phase diagram displayed in Figure 1b summarizes the solubility-composition dependence of the C₆₀:C₇₀:*o*-DCB system: (1) a single-phase region at concentrations above the liquidus line, which yields homogeneous solutions (Figure 1b; region A), and (2) a two-phase region, which is characterized by saturated solutions and aggregates of excess fullerene material (Figure 1b; region B).

In order to investigate the quality of pristine fullerene solutions in more detail we carried out diffusion measurements by pulsed gradient ¹³C-NMR spectroscopy. For C_x:*o*-DCB binary solutions with a concentration of 10 and 20 g L⁻¹ we find a self-diffusion coefficient *D* of 3.9·10⁻¹⁰ m² s⁻¹ for C₆₀ and 3.7·10⁻¹⁰ m² s⁻¹ for C₇₀ (see Supporting Information, Figure S1). These values are in good agreement with the self-diffusion coefficients that can be expected for molecules with a spherical (C₆₀) or prolate (C₇₀) geometry according to the Stokes-Einstein relation, which predicts values within ± 20 % of the experimental results depending on the selected boundary conditions (see Supporting Information for details). We thus conclude that in the binary solutions the pristine fullerenes are molecularly dissolved. For ternary solutions we were able to extract the individual self-diffusion coefficients of both C₆₀ and C₇₀ at concentrations below as well as above the solubility limit of the individual components (cf. Figure 1). Below the solubility limit we observe good agreement between binary and ternary solutions for a low concentration of 10 g L⁻¹, indicating that C₆₀ and C₇₀ tend to remain molecularly dissolved upon mixing. For higher concentrations of 20, 35 and 50 g L⁻¹ a slight deviation of no more than 10 % is observed from values that are predicted for solid spheres. This slight decrease in diffusivity may arise from the formation of minor fractions of aggregates of 2, 3, 4, *etc.* fullerene molecules, which would comprise 19 %, 11 %, 9 %, *etc.* of the C₆₀:C₇₀ mixture (see Supporting Information for details). Therefore, we conclude that a fine, close-to-molecular distribution is maintained in C₆₀:C₇₀:*o*-DCB ternary solutions even above the solubility limit of C₆₀:*o*-DCB and C₇₀:*o*-DCB binaries.

In order to examine the suitability of the here investigated fullerene mixtures as n-type semiconductor materials, we studied the impact of their mixing on electron transport. To this end we prepared bottom-gate, top-contact (BG-TC) field-effect transistors (FETs). Devices were fabricated by spin-coating *o*-DCB solutions of pristine fullerenes, to which we added about 9 wt% ultra-high molecular weight polystyrene (UHMW-PS) as a binder to ease film formation.^[14] Remarkably, reference films based on either C₆₀ or C₇₀ dewet during spin-coating, whereas the use of C₆₀:C₇₀ mixtures resulted in even film coverage (**Figure 2a**). This observation may be explained by the reduced tendency of fullerenes to crystallize upon mixing, which is well documented for substituted fullerenes (PCBM)s and leads to the formation of disordered thin films.^[15-17] We note that as a result of improved film formation FETs based on fullerene mixtures allow for greater reproducibility. The FET device characteristics are largely independent of the fullerene ratio with a threshold voltage $V_{th} \sim 6-7$ V and an ON-OFF ratio of 10⁵ (see Figure 2b,c for transfer and output characteristics). We extract a saturated electron mobility of $\mu_e \sim 1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ that is independent of the C₆₀:C₇₀ ratio (Figure 2d). Evidently, the here investigated fullerene mixtures feature excellent charge transport properties, which are on par with results reported for solution-processed pristine fullerenes.^[5, 18] It is worth noting that the absence of ordered domains (see Supporting Information Figure S2), combined with the high symmetry of the fullerene molecules, implies several attractive features such as the absence of grain boundaries, which can impede charge transport, as well as isotropic device characteristics.^[19]

We further explored the use of pristine fullerene mixtures as an acceptor material for polymer solar cells. Devices were fabricated with standard geometry (see inset **Figure 3a**) using a widely studied narrow-bandgap fluorothieno-benzodithiophene copolymer (PTB7) as the donor material.^[20-22] Active layers were prepared by first co-dissolving PTB7 with

mixtures of pristine fullerenes in *o*-DCB, using concentrations of 30-40 g L⁻¹, followed by spin-coating to form ~ 90-150 nm thin films (see Experimental Section for details).

Initially, we investigated the influence of the polymer:fullerene stoichiometry (using a fixed 1:1 C₆₀:C₇₀ ratio) and found that equal amounts of donor and acceptor material resulted in solar cells with the highest performance (Supporting Information, Figure S3). Therefore, for all remaining experiments we used a 1:1 PTB7:fullerene stoichiometry but varied the C₆₀:C₇₀ ratio. While all 1:1 PTB7:fullerene photovoltaic devices display a similarly high fill factor $FF \sim 0.6$ and an open-circuit voltage $V_{oc} \sim 0.66$ V, the short-circuit current density J_{sc} varied more strongly with C₆₀:C₇₀ ratio. The PTB7:C₆₀ binary mixture delivered the lowest $J_{sc} \sim 11.9$ mA cm⁻² (Figure 2a), which we ascribe to the weaker absorption of C₆₀ as compared to C₇₀ across the 360-650 nm region.^[11] This observation is supported by the corresponding external quantum efficiency (EQE) spectra (Figure 2b), which confirm that the replacement of C₆₀ by C₇₀ allows for larger photocurrent generation in the 360-650 nm region. In fact a J_{sc} as high as 14.9 mA cm⁻² is achieved for 2:1:1 PTB7:C₆₀:C₇₀, which is comparable to PTB7:PC₇₁BM solar cells with a similar device architecture.^[20, 21] The higher FF reported by Lu *et al.* was obtained with a higher molecular-weight PTB7 ($M_n \sim 128$ kg mol⁻¹), which led to a considerable increase in the PCE of PTB7:PC₇₁BM based solar cells.^[21] We therefore propose that the here observed $FF \sim 0.6$ is not an inherent limitation of the pristine fullerene mixture itself, as corroborated by the high field-effect electron mobilities, discussed in the previous section, but mostly due to the lower molecular weight of the PTB7 used in this study ($M_n \sim 34$ kg mol⁻¹).

We observe that the open-circuit voltage $V_{oc} \sim 0.66$ V is independent of the fullerene ratio (see Figure 3a and Table 2). The use of pristine fullerenes leads to a ~ 0.1 V reduction in V_{oc} as compared to PCBM-based devices.^[21] This is consistent with our previous work on solar cells based on a thiophene-quinoxaline copolymer (TQ1).^[11, 23] To understand whether

the open-circuit voltage of PTB7:C₆₀:C₇₀ based solar cells is inherently limited by our choice of materials we carried out a more detailed investigation. We rely on the empirical rule that the V_{oc} of organic solar cells is directly related to the energy of the charge-transfer (CT) state E_{CT} , which we estimate by fitting the lower energy part of Fourier-transform photocurrent spectroscopy (FTPS) spectra, which originates from an excitation in the CT manifold.^[24, 25] We find an $E_{CT} \sim 1.26$ eV that is largely unaffected by the fullerene ratio (Figure 3c), which is consistent with our observation that the C₆₀:C₇₀ ratio does not affect the open-circuit voltage of the corresponding solar cells. We thus conclude that the open-circuit voltage obtained with the here investigated PTB7:C₆₀:C₇₀ ternary blends is inherently limited by the choice of materials, i.e. a $V_{oc} \sim 0.66$ V is likely the upper limit for optimized photovoltaic devices based on PTB7 and pristine fullerenes.

Overall, we obtained a PCE of 4.9 % for devices based on C₆₀, whereas devices based on C₇₀ or the mixture C₆₀:C₇₀ yielded a PCE of 6 %, with champion solar cells of 6.5% for the ternary blend (Table 2). Since the C₆₀:C₇₀ ratio that is obtained during fullerene synthesis can range from 4:1 to about 4:3.2, depending on the preparation route,^[10, 11] we also tested 5:4:1 PTB7:C₆₀:C₇₀ devices, which yielded a comparably high PCE of 5.1%. To the best of our knowledge, these are the highest reported PCE values for a polymer solar cell employing pristine fullerenes as the acceptor. Moreover, we find that solar cells based on PTB7:C₆₀:C₇₀ are highly reproducible, as evidenced by a comparison of a total of 36 devices (Figure 3d), and thermally stable, which we tested by annealing the active layer for 10 min at 100 °C prior to the deposition of the top electrode (see Table 2). Certainly, both of these properties are highly desirable for the future upscaling of organic photovoltaic technology.

In order to examine the nanostructure of the here investigated active layer blends in more detail we carried out transmission electron microscopy (TEM) and photoluminescence (PL) spectroscopy. To this end, we spin-coated thin films from *o*-DCB solutions with a total

materials content of 30 g L⁻¹, which also yielded some of the most efficient solar cells (cf. Table 2). Whereas for this concentration the solubility limit of C₆₀ has been reached, C₇₀ remains mostly soluble (cf. Figure 1). Instead, for C₆₀:C₇₀ ratios ranging from 4:1 to 1:4 full solubility can be anticipated. Independent of the C₆₀:C₇₀ ratio, TEM images indicate a fine-grained/homogeneous nanostructure and the absence of fullerene crystals, as corroborated by the corresponding electron diffraction patterns, which only feature a broad, amorphous halo (Supporting Information, Figure S4). The fine-grained nanostructure is further corroborated by PL spectroscopy. The efficiency of excitation quenching can be defined by the PL quenching ratio Ψ , i.e. the ratio of the integrated PL spectra of neat PTB7 and the PTB7:fullerene blend (see Experimental Section). For 1:1 PTB7:C₆₀ we determine a PL quenching ratio of $\Psi \sim 150$, which indicates a well-intermixed nanostructure of this binary blend (Supporting Information, Table S1). Instead, for ternary blends with a C₆₀:C₇₀ ratio between 4:1 and 1:4 as well as for 1:1 PTB7:C₇₀ we observe significantly higher values of $\Psi > 240$, which suggest an even finer distribution of the fullerene acceptor material for these more soluble blend ratios. Evidently, pristine fullerenes and in particular fullerene mixtures can be used as the electron acceptor material in polymer:fullerene bulk-heterojunction blends without causing any apparent phase separation, in agreement with the high EQEs and short-circuit current densities of the corresponding photovoltaic devices.

Finally, we argue that the concept of ‘entropic dissolution’ is applicable to other organic semiconductor mixtures. In order to substantiate this claim we carried out a final set of experiments to investigate the solubility of one very different system based on rubrene and 5,12-diphenylanthracene (DPA) in toluene at 27 °C, which Stingelin et al. have employed to spin-coat glassy films that can be carefully crystallized through thermal annealing to form the active layer of FETs.^[14] We observe a substantial increase in solubility with a maximum at a 1:3 rubrene:DPA molar ratio (Supporting Information, Figure S5),

which coincides with the range of compositions that display the highest tendency to vitrify (cf. Ref. [14]). In contrast to C₆₀:C₇₀ the maximum solubility does not occur at a 1:1 volume ratio, indicating that besides the configurational entropy of mixing also differences in the conformational entropy of rubrene and DPA as well as, potentially, molecular interactions must be considered. We conclude that judicious co-dissolution of organic semiconductor mixtures is a general approach that can be used to enhance the solubility and, in addition, is highly relevant for designing optimal processing schemes for, e.g., glass-forming alloys.

Table 2. Performance of optimized solar cells: total concentration of solid material in *o*-DCB prior to spin-coating, number of measured devices, thickness of the active layer, short-circuit current density J_{sc} , open-circuit voltage V_{oc} , fill factor FF and power-conversion efficiency PCE (champion results in brackets).

Blend	Total conc. / g L ⁻¹	No. of devices	Thickness / nm	J_{sc} / mA cm ⁻²	V_{oc} / mV	FF / -	PCE / %
1:1 PTB7:C ₆₀	40	6	~ 90	11.9±1.2	668±1	0.61±0.03	4.9±0.6 (5.7)
1:1 PTB7:C ₇₀	40	6	~ 90	14.6±0.6	664±1	0.62±0.01	6.0±0.3 (6.4)
5:4:1 PTB7:C ₆₀ :C ₇₀	40	6	~ 120	14.3±0.6	663±1	0.53±0.01	5.1±0.3 (5.4)
2:1:1 PTB7:C ₆₀ :C ₇₀	40	6	~ 150	14.4±0.7	663±1	0.62±0.01	6.0±0.3 (6.5)
2:1:1 PTB7:C ₆₀ :C ₇₀	30	24	~ 120	14.9±0.8	660±1	0.60±0.03	5.9±0.6 (6.5)
2:1:1 PTB7:C ₆₀ :C ₇₀ [*]	30	6	~ 120	14.1±0.1	663±1	0.62±0.01	5.9±0.3 (6.2)

*annealed for 10 min at 100 °C

Table of contents

The solubility of pristine fullerenes can be enhanced by mixing C_{60} and C_{70} due to the associated increase in configurational entropy. This ‘entropic dissolution’ allows to prepare field-effect transistors with an electron mobility of $1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ and polymer solar cells with a highly reproducible power-conversion efficiency of 6 % as well as a thermally stable active layer.

Keywords: fullerenes, solubility, configurational entropy, field-effect transistors, organic solar cells

A. Diaz de Zerio Mendaza, A. Melianas, S. Rossbauer, O. Bäcke, L. Nordstierna, P. Erhart, E. Olsson, T. D. Anthopoulos, O. Inganäs, C. Müller*

High-entropy mixtures of pristine fullerenes for solution-processed transistors and solar cells
