Three-dimensional dandelion-shape TiO₂/Multi-layer graphene compound (TiO₂/MLG) composed of TiO₂(B) fibrils and anatase pappi structures has been synthesized as potential anode material for Li storage. Electronmicroscopy indicates that the composite contains triphase boundaries between anatase, TiO₂(B) and graphene, which are responsible for the enhancement of energy storage and the decrease of electrode polarization. Cyclic voltammetric investigations indicate that both Li⁺ insertion and pseudocapacitance contribute to charge storage. Ultrahigh specific capacities of 243 and 182 mAh g⁻¹ have been obtained at 0.1 and 1 A g⁻¹, respectively. Moreover, the excellent capacity retention can reach 99.6% after 100 cycles with almost 100% coulombic efficiency at 0.1 A g⁻¹. The importance of the triphase boundary in enhancing the storage of charge and transport of Li⁺ is demonstrated.

Introduction

As a consequence of an increasing demand for energy, improved energy storage is required to enable future power systems. Lithium-ion batteries offer high energy and power density and as a result are attracting great interest with a focus on designing electrodes that can enhance energy-storage performance^{1, 2}. Titanium dioxide (TiO₂), one of the most promising anode materials, has been intensively studied, not only due to its low cost, abundance and non-toxicity but also on account of the negligible volume deformation during the Li-ion insertion/de-insertion processes (intercalation is preferred to describe lithium storage in a lamellar host structure)³ and excellent gravimetric capacity³⁻⁵. The operational potential of TiO₂ is high (>1 V vs. Li⁺/Li), which can enhance battery safety by reducing the probability of the formation of lithium dendrites at the anode surface and avoid to form the solid electrolyte interface (SEI)⁶⁻⁸. To-date various polymorphs of TiO₂ including anatase (tetragonal)⁹, rutile (tetragonal)⁵, brookite (orthorhombic)¹⁰ and bronze (TiO₂-B, monoclinic)¹¹ have been extensively studied as anode materials in lithium-ion batteries. The other allotropes; which either are easily transformed to other types like ramsdellite(TiO₂-R)¹² and hollandite (TiO₂-H)¹³ or need high-pressure and high-

temperature synthesis conditions, such as α-PbO₂-structured TiO₂(II)¹⁴, baddeleyite¹⁵, columbite¹⁶, cubic¹⁷, TiO₂(OI)¹⁸ and TiO₂(OII)¹⁹; have been rarely researched. Despite the numerous studies, TiO₂ has not been used extensively as a high rate anode material owing to a limited ability to store charge and its poor conductivity.

An intrinsic drawback of TiO₂ is the material's poor electronic conductivity (10⁻¹³ S cm⁻¹)^{5, 20, 21} and limited ionic conductivity²². Several solutions have been proposed to overcome this issue including: (i) addition of a conducting phase, e.g., carbon coating²³ or compositing with transition metal oxides²⁴, (ii) reduction of the ionic diffusion length by fabricating nanoscale TiO₂ structures such as wires²⁵, tubes²⁶, cubes²⁷, rods²⁸ and flowers⁸, (iii) doping through either the introduction of Ti³⁺ or oxygen vacancies^{5, 29} or with heteroatoms B³⁰, C⁶, N³¹, S³², Ni³³, Zn³⁴ or Sn³⁵. Charge stored in a Li⁺/heterophase anode system may be enhanced³⁶⁻³⁹ through interfacial charge storage at both the solid-liquid interface and internal solid-solid interfaces. Jamnik and Maier have demonstrated increased charge storage at TiO₂-metal interfaces as a result of the metal acting as an electron sink and the TiO₂ storing excess Li⁺. In TiO₂ photochemical studies, it has been demonstrated that owing to the offset in the conduction band levels, photogenerated charge carriers can be stored at the junction between anatase and TiO₂(B)⁴⁰⁻⁴². This band offset has been employed in TiO₂ engineering to yield a material in which Li⁺ and electrons are separated across TiO₂(B)/anatase TiO₂ interfaces within the anode leading to increased charge storage.

In the present work we have fabricated a new TiO₂-graphene composite designed to enhance the prospects of this low cost,

abundant, non-toxic material as an anode in a Li-battery. The TiO_2 is dandelion shaped with nanosized $\text{TiO}_2(\text{B})$ fibrils capped with anatase TiO_2 pappi. The as-prepared structure has extensive solid-electrolyte and solid-solid junctions to maximize interfacial charge storage. Multilayered graphene (MLG) is added to the TiO_2 phases to yield a composite with enhanced conductivity and an increased number of solid-solid junctions.

Experimental

Materials preparation: Dandelion-shape TiO_2 /Multi-layer graphene (TiO_2 /MLG) and compared TiO_2 anode materials were synthesized by solvent-thermal method. For TiO_2 /MLG preparation, 0.24g polyvinylpyrrolidone (PVP, Sigma, average mole weight: 360000.) was dissolved into 40 mL acetic acid solution (Sinopharm Chemical Reagent Beijing Co. Ltd.) by strong stirring, following with the addition of 0.05g multi-layer graphene ($\sim 10\text{nm}$ thickness, Hefei Weijing Material Technology Co. Ltd.) and continuous stirring for 20 min. Then, 1 mL tetrabutyltitanate (TBT, Sinopharm Chemical Reagent Beijing Co. Ltd.) was added dropwise to the above dark solution in 5 min, and the mixture was sealed to sonicate at a power of 99W for 20 min at 50°C . The obtained suspension was transferred to a 60 mL Teflon-lined stainless-steel autoclave, and maintained at 150°C for 24 h. After being cooled to room temperature, the precipitate was collected by centrifuge, washed with ethanol and water for several times and dried at 60°C in an oven. The dried sample was then calcined in the tube furnace at 400°C for 4 h flowing with argon atmosphere, and the temperature rose from room temperature with an increase rate of $3^\circ/\text{min}$. After grinding, the TiO_2 /MLG powder was obtained. The compared TiO_2 sample was prepared in the same method but without the use of multi-layer graphene.

Characterization: The crystallographic structure of the as-prepared materials was studied by X-ray powder diffraction (XRD) using a Bruker D8 diffractometer with monochromatic $\text{Cu K}\alpha$ radiation ($\lambda=1.5406\text{ \AA}$), and the diffraction data was recorded in the 2θ range of $10\text{--}80^\circ$. The morphological structures of the anode materials were investigated by a FEI Quanta 200 scanning electron microscopy (SEM) and JEOL 2010F transmission electron microscopy (TEM). The thermogravimetric analysis/differential scanning calorimetry (TGA/DSC) of the samples was carried out on a Diamond TG thermo-analyzer.

Electrochemical tests: The anode was fabricated with the active material, acetylene black, and binder (Polyvinylidene Fluoride, PVDF) in a weight ratio of 8:1:1 by using NMP as solvent and an copper foil as current collector ($\sim 2.5\text{ mg}/\text{cm}^2$), followed by drying in vacuum at 110°C for 24 h. The R2016 coin cell was assembled in an argon-filled glove box using metallic lithium as the cathode and Celgard 2500 membrane as separator. The electrolyte was 1 M LiPF_6 dissolved in a mixture of ethylene carbonate (EC), dimethyl carbonate (DMC), diethyl carbonate (DEC) (v/v/v, 1/1/1). Cyclic voltammetry (CV) and galvanostatic charge/discharge cycling tests were carried out

in a setting voltage range by using an electrochemical workstation (CHI660C) and a CT2001A LAND battery tester, respectively. Electrochemical impedance spectroscopy (EIS) was studied using a Modulab (Solartron Analytical) with the amplitude of 5 mV in the frequency range from 1 MHz to 10 MHz. All electrochemical tests were carried out at room temperature.

Results and discussion

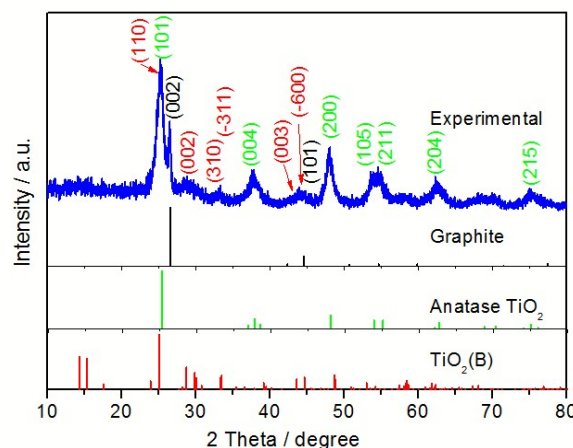

Figure 1. XRD patterns of the as-prepared sample.

The X-ray diffraction (XRD) pattern of the as-prepared composite is shown in Figure 1. The diffraction pattern can be indexed to the three constituent phases of the composite, namely graphite (P63/mmc, JPCD No.65-6212), anatase TiO_2 (I41/amd, JPCD No.65-5714) and $\text{TiO}_2(\text{B})$ (C2/m, JPCD No.46-1238). The observed graphite peak is evidence of the incorporation of the multi-layer graphene (MLG) which was used as a reagent during the preparation. The strong (002) diffraction peak at 26.5° illustrates that the MLG structure was maintained throughout the hydrothermal and calcination processes employed in fabrication^{43,44}. $\text{TiO}_2(\text{B})$ is formed from the thermal dehydration of layered hydrogen titanate^{45, 46}, resulting from the low-rate of hydrolysis of TBT in acetic acid. The slow hydrolysis of the TBT precursor with the help of the PVP dispersant is beneficial for the self-assembly of anatase and $\text{TiO}_2(\text{B})$. Rietveld refinement of the diffraction pattern using a two-phase analysis model, see **Figure S1**, indicates that the phase content of anatase TiO_2 and $\text{TiO}_2(\text{B})$ are 70.7% and 29.3%, respectively.

In order to estimate the amount of MLG in the composite sample, thermal analysis/differential scanning calorimetry (TGA/DSC) was carried out in air with a heating speed of 5°C min^{-1} (**Figure S2**). The slight weight loss before 120°C is ascribed to the evaporation of adsorbed water molecules. As the complete decomposition temperature of graphene has been generally considered to be around 700°C ⁴⁷⁻⁵⁰, the weight loss at this temperature has been assumed to correspond to the content of MLG in the TiO_2 /MLG composite, which is estimated to be 5.8%. In addition, the wide exothermic peaks of TiO_2 /MLG reflects the oxidation of the carbon skeleton of

MLG, which can be affected by the formed C-Ti bond and the distribution of TiO₂ creating localized spots to facilitate the oxidation reaction⁵¹⁻⁵³. Besides MLG, the phase transformation of TiO₂ from TiO₂(B) to anatase to rutile in the range of 350 ~ 600 °C causes fluctuations in the exothermic peaks^{54, 55}.

Figure 2. a) TEM image of TiO₂/MLG morphology. b) Magnified TEM image around outer region of TiO₂/MLG. c) Corresponding SAED pattern of the rectangular area in b). A and B represent anatase TiO₂ and TiO₂(B), respectively. d) HRTEM image with interface lines between phase regions. A, B and G in the image indicate anatase TiO₂, TiO₂(B) and graphene phase, respectively. e) Representation of the interface mismatch rate, δ , between two adjacent phases. f) HRTEM image of the focused limb part with magnified lattice plane by FFT and inverse FFT.

The dandelion-shaped TiO₂/MLG with TiO₂(B) fibrils and anatase TiO₂ pappi was characterized by scanning electron microscopy (SEM) and transmission electron microscopy (TEM). **Figures 2(a) and (b)** show that TiO₂/MLG is composed of connected ultrathin nanowires and nanosheets, with a thickness of several nanometers. The SEM image of TiO₂/MLG is shown in **Figure S3** with the spherical dandelion morphology. The selected area electron diffraction (SAED) pattern shown in **Figure 2c** displays broad diffraction rings that can be assigned to a composite of the two TiO₂ polymorphs, namely anatase TiO₂ and TiO₂(B), and the broad rings assigned to (110), (202), (020), (113), (-621) and (423) planes for TiO₂(B) can also be identified to the (101), (103), (200), (105), (204) and (224) planes of anatase TiO₂⁴. The high resolution transmission electron microscope (HRTEM) image of TiO₂/MLG displayed in **Figure 2d** clearly demonstrates the crystal domains of the three phases in a nano-region, and the boundary structures between anatase TiO₂ and TiO₂(B). Within the triple phase region indicated by an ellipse in **Figure 2(d)**, it

is found that the lattice fringes of the (003) plane of TiO₂(B) and the (004) plane of anatase TiO₂ are adjacent with a 125° angular mismatch, and there is a 5° angular mismatch between the (100) plane of graphene and the (003) plane of TiO₂(B) and 120° between the (100) plane of graphene and the (004) plane of anatase TiO₂. As depicted in **Figure 2e**, the interface mismatch rate, δ , between two mismatched phases can be calculated using equation 1 where δ reflects the interface matching intensity or the possibility of interface match⁴.

$$\delta = 1 - \frac{d_2 |\cos \theta|}{d_1} \quad d_1 \geq d_2 \quad (1)$$

the schematically presented parameters d_1 and d_2 signify the projected lengths of mismatched planes and equation 1 may be employed when $d_1 \geq d_2$. δ is calculated to be 0.497, 0.032 and 0.539 for the interfaces between the (003) plane of TiO₂(B) and the (004) plane of anatase, the (003) plane of TiO₂(B) and (100) plane of graphene, the (004) plane of anatase and (100) plane of graphene, respectively. More abundant interfacial structure is present between graphene and anatase in this triphase composite than between anatase and TiO₂(B). By employing Fast Fourier Transform (FFT) and inverse FFT, the magnified lattices of the corresponding darker parts in the HRTEM image displayed in **Figure 2f** are assigned to TiO₂(B), which demonstrates that crystals of this phase form the fibrils whilst the lighter pappi parts are composed of anatase TiO₂ and the complementary analysis is shown in **Figure S4**. In addition, it is clearly observed from the FFT images in **Figure 2f** that the lattice plane of (-604) displays a degree of disorder.

Cyclic Voltammetry (CV) of TiO₂/MLG was implemented in a voltage range of 1-3 V vs. Li/Li⁺, and the CV curves are shown in **Figure 3a,b**. The first CV cycle, beginning from the open circuit voltage, shows different electrochemical behavior to the subsequent cycles, consistent with conditioning of the anode material during the first round of Li insertion/deinsertion. The second and fourth cycles are consistent in shape illustrating excellent reversibility of the reactions for the as-prepared material^{4, 7}. The cathodic peak located at 1.37 V vs. Li/Li⁺ in the first cycle is found to disappear in the following, which has been explained as the irreversible reactions of some impurities⁴. Compared with the CV peaks of TiO₂(B)⁷, the cathodic peak at around 1.4 V in the first cycle results from the open channel saturation of TiO₂(B) by inserted Li⁺ ions. In the anodic scan of the second cycle there are three distinct peaks labeled A, B1 and B2 in **Figure 3(a)**. At higher scan rate, **Figure 3(b)**, peaks B1 and B2 are less well defined and eventually merge into a single entity labeled B. Analysis of peaks A and B as the scan rate is varied from 0.2 mV s⁻¹ to 1.2 mV s⁻¹ indicates that the peak current of the former is a linear function of the square root of the scan rate, **Figures 3(c)**, whilst the height of the latter is directly proportional to the scan rate, **Figure 3(d)**. The as-prepared TiO₂/MLG includes a mixture of anatase and TiO₂(B) presenting diffusion- and surface-controlled electrochemical reactions at different potentials^{3, 4, 7}. The position of peak A, 1.68 V vs. Li/Li⁺, and the variation in peak height with scan rate are consistent with lithium insertion into anatase TiO₂⁵. Peak B can be assigned to a pseudocapacitive

Figure 3. CV curves of TiO₂/MLG. a) The first four cycles at the scan rate of 0.2 mV s⁻¹. b) CV curves at different scan rates from 0.2 to 1.2 mV s⁻¹. Linear relationships of c) the A peak

process on the surface of TiO₂(B)⁵⁶. A higher current associated with anatase TiO₂ is in agreement with the composition of the composite.

The galvanostatic charge/discharge profiles in the voltage range of 1 to 3V vs. Li/Li⁺ of TiO₂/MLG and TiO₂ prepared using the same synthetic method but without MLG are shown in **Figure 4a**. The discharge curves of TiO₂/MLG and TiO₂ can be divided into three regions^{36,57}. The first region (Region1) with a steep decrease in potential is ascribed to the homogeneous Li⁺ insertion into bulk TiO₂ until the solid-solution limit of Li⁺ ions in TiO₂, such behavior is indicative of a nano-sized titania material⁵⁸. Region 2 is characteristic of the lithiation of anatase. It can be seen that the average voltage plateau of TiO₂/MLG (1.75 V) is 20 mV higher than that of TiO₂ (1.73 V), from which it can be deduced that the boundary structures between TiO₂ and graphene have the potential to lower the electrode polarization resulting from the good electronic and ionic conductivity⁴⁴ in the biphasic TiO₂ (Li-rich and Li-poor) co-existence plateau³⁶. The contributed capacities of 126 and 106 mAh g⁻¹ for TiO₂/MLG and TiO₂ in the two regions result from the random insertion of Li⁺ into over half the available interstitial octahedral sites of anatase^{4,57}. Region 3, at low potentials, corresponds to the loss of pseudocapacitive charges from the interfaces in the system. The TiO₂/MLG composite anode and the TiO₂ anode have very similar behavior in regions 1 and 2 of the discharge curve indicating that the degree of lithiation of the nanoparticles is independent of the amount of MLG. In region 3 the TiO₂/MLG composite displays a higher specific capacity at all potentials. In the second and third cycles, region3 of TiO₂/MLG composite can be divided into two slopes of different gradient whilst for the TiO₂ anode a single gradient is observed, as shown in **Figure S5**. The coulombic efficiency of TiO₂/MLG in the first cycle is 80.4%, slightly higher than the 78.8% observed for the TiO₂ anode.

Figure 4b shows the discharge capacities of TiO₂/MLG at current densities of 0.05, 0.1, 0.2, 0.5, 1, 2, 3 and 5 A g⁻¹ are 266, 243, 221, 200, 182, 161, 140 and 115 mAh g⁻¹. For the higher discharge rates of 5.5, 6, 7, 8, and 10 A g⁻¹ the capacities of TiO₂/MLG are 84, 69, 48, 43 and 35mAh g⁻¹, as indicated in **Figure 4c**. For comparison, the specific discharge capacities of TiO₂ displayed in **Figure 4d** are 198, 183, 159, 128, 119, 113, 100 and 86 mAh g⁻¹ for current densities of 0.05, 0.1, 0.2, 0.5, 0.8, 1, 1.4 and 2 A g⁻¹, respectively. It is found that the specific capacity of TiO₂/MLG at 1 A g⁻¹ retains 75% of the value at 0.1 A g⁻¹, while TiO₂ keeps 62%. The cyclic performances of TiO₂/MLG in **Figure 4e** was investigated to evaluate the electrode stability. Only a slight loss of capacity was observed after 100 cycles at a current density of 0.1 A g⁻¹. The corresponding capacity retention of TiO₂/MLG is 99.6% with high coulombic efficiency almost approaching 100%, even for high current rates of 5 and 10 A g⁻¹ as illustrated in **Figure S6**. The coulombic efficiencies of the 1200 cycles of TiO₂/MLG are extreme coincident when compared with that of the reference TiO₂ (**Figure S7**), which confirms the high electrode stability of TiO₂/MLG during cycling. With reference to the conclusions from Wu *et. al*⁴, the high electrochemical stability of the

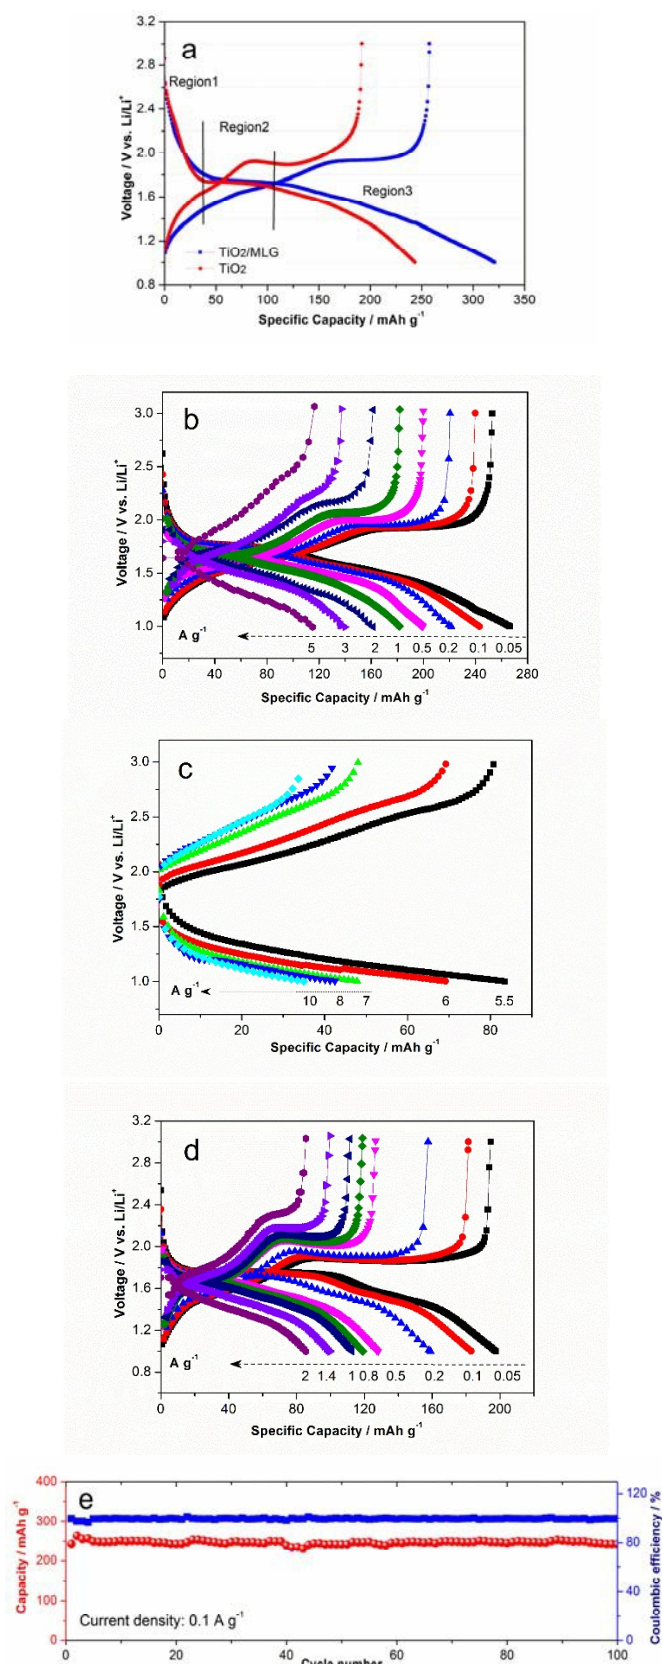

Figure 4. Galvanostatic charge/discharge profiles. a) The first cycle of TiO_2/MLG and TiO_2 at a current density of 0.05 A g^{-1} . b) Rate performances of TiO_2/MLG from 0.05 to 2 A g^{-1} and c) from 5.5 to 10 A g^{-1} . d) Rate performances of TiO_2 from 0.05 to 2 A g^{-1} . e) Cycling performances of TiO_2/MLG at 0.1 A g^{-1} .

electrode is attributed to the three-dimensional dandelion-shape microsphere structure which provides short diffusion distance for ion transport, high contact area between the electrolyte and electrode and the boundaries of TiO_2/MLG which are capable of accommodating strain during cycling, leading to high Li^+ diffusion kinetics as well as stable electrochemical reactions.

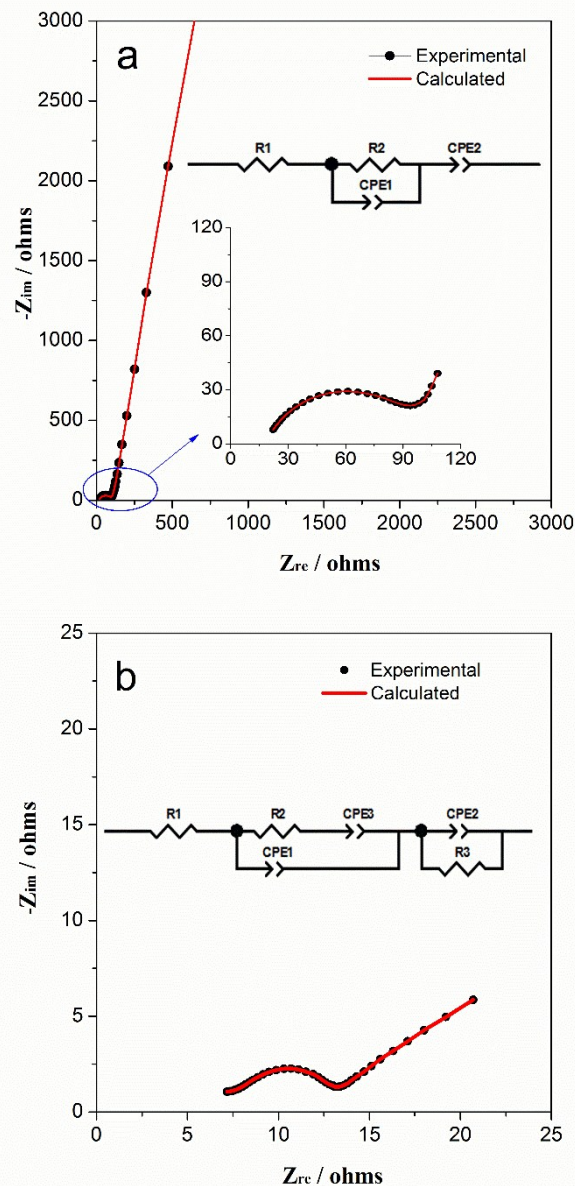

Figure 5. Nyquist plot of TiO_2/MLG cell after a) 0 and b) 1000 cycles with corresponding calculated fitting results. Inset is the corresponding equivalent circuit model.

Electrochemical impedance spectroscopy (EIS) was used to explore the variation of impedance of TiO_2/MLG during electrochemical cycling. **Figures 5(a)** and **(b)** show the Nyquist plots for electrodes cycled 0 and 1000 times with corresponding calculated plots which are obtained from the equivalent circuit model in the insert, respectively. For the

components in the equivalent circuit, the values, with errors, that were calculated to yield the best fits to the experimental data are listed in **Table S1** and **S2**. In the equivalent circuit of both, R1 represents the internal resistance of the cell that arises from both the electrode and electrolyte. CPE2 (constant phase element) in **Figure 5(a)** represents the pseudocapacitance that is generated on the complicated surface of internal triphase boundaries⁴ plus electrodes. R2 represents the charge transfer and possible ion diffusion, and CPE1 is the capacitor in the bulk associated with Li⁺ ions insertion. In **Figure 5(b)**, two new components are introduced namely CPE3 and R3. CPE3 is defined as Warburg resistance with the factor, $n=0.5$ (**Table S2**) and correspondingly, CPE1 becomes pure capacitor with $n=1$. Warburg resistance results from the solid-state ion diffusion in the electrode channels. The presence of R3 points to the development of a surface resistance during cycling, which can be attributed to the open interfacial structure in the electrode or SEI film on the electrode surface⁴. According to **Table S1** and **S2**, the resistances, R1 and R2 have decreased but the capacitance of CPE1 and CPE2 have increased after multiple electrochemical cycles when compared with those of the fresh cell. The impedance data indicates that the structural rearrangement of TiO₂/MLG electrode during cycling promotes the boundary storage to be predominant over bulk storage for Li⁺ ions. The interfacial structure provides more open channels for ion diffusion with cycling.

Figure 6. Schematic representation of interfacial storage for Li⁺ ions of TiO₂/MLG.

Figure 6 is a schematic representation of the TiO₂/MLG composite. The as-prepared material has an abundance of tri-phase boundaries between anatase TiO₂, TiO₂(B) and graphene. Wang *et al.*⁴² have demonstrated that charge storage at the anatase TiO₂-TiO₂(B) junction can enhance Li⁺ storage in anode materials. The high specific capacities observed for the biphasic TiO₂ material prepared in the absence of MLG points to a synergistic interfacial effect improving charge storage. The specific capacitance of the dandelion structured TiO₂ is further enhanced when MLG is introduced into the composite. The interfaces within nanosized materials can offer more sites for Li⁺ storage³⁶ and the boundaries between MLG and TiO₂ phases also provide sites for Li storage. The MLG itself with nearly 30 layers will only contribute negligible capacity in the voltage range of 1-3 V vs. Li/Li⁺. There are abundant phase boundaries arising from the polycrystal in TiO₂/MLG dandelion structure, contributing to large extent of lattice mismatch, as well as extra sites for Li⁺

ion and electron storage and some disordered planes probably provide more active sites for Li⁺ ion storage and transfer. The TiO₂/MLG is able to store charge through both Li⁺ insertion and a pseudocapacitive mechanism, as evidenced by the *i*-V curves obtained when the potential is cycled. We postulate that the improved rate performance of the TiO₂/MLG composite relative to the TiO₂ material results from the fact that the edge-abundant interfaces of graphene can promote the Li⁺ ion diffusion and electron transport along the triphase boundaries, as schematically presented in **Figure 6**.

Conclusions

Dandelion-shape TiO₂/MLG composed of TiO₂(B) fibrils and anatase pappi was synthesized as promising anode material for Li storage. Both the material characterization and cyclic voltammetry presenting diffusion- and surface-controlled electrochemical reaction at different potentials, evidenced the anatase/TiO₂(B) heterophase in TiO₂/MLG, and the open channel saturation of TiO₂(B) by inserted Li⁺ ions at around 1.4 V was used to explain the irreversible cathodic peak. A mismatch rate, δ , between two adjacent phases with mingled boundaries, was introduced to describe the interplanar mismatch degree. The edge-abundant interfaces of graphene involved in the triphase boundaries were reported to enhance the electrochemical storage properties of TiO₂/MLG and lower the electrode polarization by the improvement of Li⁺ diffusion and electron transport. The discharge capacities of TiO₂/MLG at current densities of 0.05, 0.1, 0.2, 0.5, 1, 2, 3 and 5 A g⁻¹ are 266, 243, 221, 200, 182, 161, 140 and 115 mAh g⁻¹, and the capacity retention is 99.6% with high coulombic efficiency almost approaching 100% after 100 cycles at the current density of 0.1 A g⁻¹. The resistances of TiO₂/MLG decreased with cycling and more boundaries were opened to enhance ionic and electron conductivity.
