## Abstract

2D materials, which are self-supporting in large areas but are only a few atoms thick, are exciting considerable interest for potential applications as diverse as electronics, molecular filtration and structural materials. Ferroelectrics have many useful applications stemming from their electrically-switchable dielectric spontaneous polarizations, including in piezoelectric devices, non-volatile memories and pyroelectric IR sensors. While 2D oxide materials are known, they have not yet received the same attention as materials such as graphene. Here we study the ferroelectricity in ultrasonically-exfoliated flakes of the layered Aurivillius oxide  $\text{Bi}_5\text{Ti}_3\text{Fe}_{0.5}\text{Co}_{0.5}\text{O}_{15}$  with a range of thicknesses. We show, for the first time, that ferroelectricity can exist in flakes with thicknesses of only 2.4nm, which is about one-half of the normal crystal unit cell. These flakes have relatively large areas (linear dimensions many times the film thickness), thus classifying them as 2D materials. Piezoresponse force microscopy (PFM) has been used to show that these very thin flakes both

1 exhibit piezoelectric effects and that the ferroelectric polarization can be reversibly switched. A new  
2 model is presented that permits the accurate modelling of the field-on and field-off PFM time-  
3 domain and hysteresis loop responses from a ferroelectric during switching in the presence of  
4 charge injection, storage and decay through a Schottky barrier at the electrode-oxide interface. This  
5 allows the extraction of parameters such as the coercive fields ( $E_c$ ), electrostrictive coefficients ( $Q_{11}$ )  
6 and spontaneous polarizations ( $P_s$ ) for the flakes. It is found that the values of  $P_s$  are around  
7  $0.04(\pm 0.02)\text{Cm}^{-2}$ , and  $Q_{11}=2(\pm 0.1)\times 10^{-2}\text{m}^4\text{C}^{-2}$ . These are in good agreement with other ferroelectric  
8 Aurivillius oxides.  $E_c$  scales with thickness ( $t$ ), closely following the semi-empirical scaling law  
9 expected for ferroelectric materials, vis:  $E_c \propto t^{-\frac{2}{3}}$ . We believe this constitutes the first evidence for  
10 ferroelectricity in a 2D oxide material, and it offers the prospect of new devices that might use the  
11 useful properties associated with the switchable ferroelectric spontaneous polarization in a 2D  
12 materials format.

## Introduction

2D materials, such as graphene, have received enormous attention over the last 10 years for their huge potential range of applications, ranging from electronics and photonics to structural materials, as has been comprehensively described elsewhere.<sup>[1]</sup> The definition of a 2D material as being one of large area but only one atom thick (e.g. graphene) has been relaxed to include materials which can exist in large area, but a few atoms and typically ca 1 unit cell or less in thickness<sup>[1a]</sup> and being self-supporting (without the necessity for a substrate). As a consequence, many 2D materials apart from graphene are being studied, such as the MoS<sub>2</sub> family. Many of these materials are semiconductors. A variety of manufacturing techniques exist<sup>[1b]</sup>, including mechanical exfoliation and direct growth. Liquid exfoliation (high shear & ultrasonic) methods offer the prospect for the low-cost production of large volumes of flakes in suspension that can subsequently be used in a variety of ways.<sup>[2]</sup> 2D functional oxides also exist and examples include simple transition metal oxides such as titania<sup>[3]</sup> and perovskite<sup>[4]</sup> La<sub>0.95</sub>Nb<sub>2</sub>O<sub>7</sub> nanosheets made by exfoliation, which have been studied for their potentially-high relative permittivities (45 to 100),<sup>[5]</sup> MnO<sub>2</sub> flakes which have received attention for battery<sup>[6]</sup> and supercapacitor applications<sup>[7]</sup> and layered tantalates such as H<sub>1.81</sub>Sr<sub>0.81</sub>Bi<sub>0.19</sub>Ta<sub>2</sub>O<sub>7</sub> being investigated for photocatalytic water splitting.<sup>[8]</sup> Recently, it has been shown that mechanically-exfoliated 2D flakes of the oxide superconductor Bi<sub>2</sub>Sr<sub>2</sub>CaCu<sub>2</sub>O<sub>8+δ</sub> exhibit superconducting transition temperatures similar to the bulk when only one-half a unit cell in thickness.<sup>[9]</sup>

Ferroelectrics (FEs) offer a range of functional properties<sup>[10]</sup> and are widely used in e.g. non-volatile memories,<sup>[11]</sup> piezoelectric RF Filters<sup>[12]</sup> and pyroelectric infra-red detectors.<sup>[13]</sup> FE switching has previously been reported in very thin films e.g. 7.5nm PVDF-TrFE copolymer films<sup>[14]</sup> and films of BaTiO<sub>3</sub> as thin as 3nm (ca 8 perovskite unit cells or “blocks”).<sup>[15]</sup> Recently, FE behavior has been reported in free-standing monolayer flakes of In<sub>2</sub>Se<sub>3</sub><sup>[16]</sup> and MoTe<sub>2</sub><sup>[17]</sup> although their spontaneous polarizations (P<sub>s</sub>) have not been quantified and the difficulties of measuring P<sub>s</sub> in such narrow band-

1 gap materials are widely acknowledged.<sup>[18]</sup> The Aurivillius oxide layer-structure materials (APMs)<sup>[19]</sup> -  
2 general formula  $\text{Bi}_2\text{O}_2(\text{A}_{m-1}\text{B}_m\text{O}_{3m+1})$  - consist of  $m$  perovskite  $\text{ABO}_3$  blocks interspersed with fluorite  
3  $\text{Bi}_2\text{O}_2$  layers. Many APMs are FE, e.g.  $\text{Bi}_4\text{Ti}_3\text{O}_{12}$ .<sup>[20]</sup> Characteristically, they have high Curie  
4 temperatures ( $>600^\circ\text{C}$ ), large in-plane  $P_s$  (ca  $0.4\text{Cm}^{-2}$ ) and in some cases small out-of-plane  $P_s$ .  
5  $\text{SrBi}_2\text{Ta}_2\text{O}_9$  ( $m = 2$ ) and  $\text{Bi}_{3.25}\text{La}_{0.75}\text{Ti}_3\text{O}_{12}$  ( $m = 3$ ) APMs have been developed for commercial use in Fe-  
6 RAM (FE random access memory) devices.<sup>[21]</sup> APMs are structurally-flexible, as many different  
7 cations can be included in the perovskite layers, and  $m$  can be varied from two up to nine.<sup>[22]</sup> <sup>[23]</sup>

8  
9  
10  
11  
12  
13  
14  
15  
16  
17 APMs are amenable starting materials for exfoliation into 2D nano-sheets.<sup>[24]</sup> However, to  
18 date there have been no studies reported of the FE properties of exfoliated APM nanoflakes. Here  
19 we report, for the first time, the study of ferroelectricity in thin exfoliated nanoflakes of the APM  
20  $\text{Bi}_5\text{Ti}_3\text{Fe}_{0.5}\text{Co}_{0.5}\text{O}_{15}$  (B5TFCO) ( $m = 4$ ) using piezoresponse force microscopy (PFM), with flake  
21 thicknesses ranging from ca 100nm down to 2.4nm. We present a model which allows extraction of  
22 the important FE parameters such as the coercive fields ( $E_c$ ), electrostrictive coefficients ( $Q_{111}$ ) and  
23 spontaneous polarizations ( $P_s$ ) in the presence of charge injection, storage and leakage with Schottky  
24 barriers at the FE oxide-electrode interfaces. We demonstrate FE switching in all the exfoliated  
25 B5TFCO nanoflakes. The switching shows very similar characteristics right across the thickness  
26 range, and persists in flakes with thicknesses of 2.4 nm and high aspect ratios (diameter 80 nm). This  
27 thickness corresponds to just over one-half unit cell or four perovskite oxide blocks plus the  
28 associated  $\text{Bi}_2\text{O}_2$  layers. We believe this demonstrates for the first time that the class of self-  
29 supporting 2D oxide materials can include FEs, with all their useful functional properties, greatly  
30 increasing the potential range of their applications.

1 PFM. SEM analysis reveals that the dispersed nano-structured flakes have plate-like morphologies,  
2 which is characteristic of the layered Aurivillius-type structures. A range of flake sizes (lateral  
3 diameters of 80 nm to 700 nm) can be observed in the SEM images (see Figure S1 for an example) as  
4 individual flakes, or stacked on top of each other or overlapped together in clusters. The two larger  
5 particles shown in Figure S1 were chosen for FIB cross-sectioning. Cross-sectional HR-TEM images of  
6 these (Figure S2) shows that these particles are clusters of flakes. Figure S2 shows the lattice images  
7 taken from these. It shows clear evidence for the expected 4-perovskite-block APM structure  
8 possessing a unit cell 4.1 nm long (*c*-axis), consistent with Figure 1. The TEM data Figure S2 shows  
9 that the larger clusters of flakes can be clustered in multi-flake aggregates.. van der Waals forces  
10 position the majority of the flakes closely parallel to the substrate surface although not all crystals  
11 are aligned perfectly flat. STEM-EDX analysis confirmed the presence of Bi and Ti in approximately  
12 the correct proportions, with the presence of low levels of Fe and Co as expected from the B5TFCO  
13 composition. This, in association with the TEM lattice images, confirms that the larger flakes  
14 maintain the APM structure. We will show that the electrical properties of the thicker flakes scale  
15 well with thickness, right down to the thinnest flakes. We believe that this is good evidence that the  
16 APM structure is maintained down to the thinnest flakes. Figure 2 presents evidence that thinner  
17 flakes can be found which are not clusters. Here we present (Figure 2a) an AFM topographic image  
18 of a single 15nm flake of B5TFCO which is lying flat in the substrate. This is nearly circular and  
19 approximately 250nm in diameter, giving it a diameter-to-thickness aspect ratio of ca17:1.

45 Electromechanical responses of the exfoliated B5TFCO flakes were assessed by simultaneous  
46 lateral and vertical PFM measurements, respectively, at a single drive frequency of 20kHz. Figure S3  
47 shows the topography (Figure S3a) of a flake ~300nm in diameter and ~33nm in height, together  
48 with the in-plane (Figure S3b – amplitude, *e* - phase) and out-of-plane (Figure S3c - amplitude, *f* -  
49 phase). It is clear from the single frequency PFM images that higher piezoresponses are obtained in  
50 the lateral direction (11 pmV<sup>-1</sup>) compared with those measured in the vertical direction (3 pmV<sup>-1</sup>).  
51  
52  
53  
54  
55  
56  
57  
58  
59 This is expected, given that the major polarization vector for APMs is along the *a*-axis.<sup>[28]</sup> The  
60  
61  
62  
63  
64  
65

1 enhanced lateral PFM response confirms that the majority of the flakes are preferentially *c*-axis  
2 oriented, with their crystallographic *a*-axes lying in the lateral plane of the film. . Given the  
3  
4 relatively low piezoresponses, topography cross-talk is likely also to have some contribution to the  
5  
6 single frequency vertical PFM images obtained. In order to amplify the weaker vertical  
7  
8 piezoresponse and reduce effects of topography cross-talk, the DART-PFM mode was used (see  
9  
10 Methods). <sup>[29]</sup>The intensified amplitude and phase responses are displayed in **Figure S3d** – amplitude  
11  
12 & **g** – phase, respectively. The magnitude of the out-of-plane response is discussed further below.  
13

14  
15  
16 In order to investigate size effects on the electromechanical properties of the exfoliated  
17  
18 B5TFCO nanoflakes, vertical DART-PFM imaging was performed on flakes with a range of lateral  
19  
20 dimensions (230nm to 2 $\mu$ m) and thicknesses (14nm to 120nm). **Figures 2b & c** show the vertical  
21  
22 amplitude and phase responses from the same flake for which the topography image is shown in  
23  
24 **Figure 2a**. The response appears to be remarkably uniform in both amplitude and phase, and  
25  
26 indicative that this flakes is single domain, although evidence for multi-domain structures was  
27  
28 observed in other flakes.  
29  
30

31  
32  
33 <sup>[30]</sup>Investigation of local room temperature FE switching in the nano-sized flakes was  
34  
35 performed by vertical DART-PFM switching spectroscopy measurements at a distinct tip position  
36  
37 after the removal of an applied pulsed DC bias (“field off state”) (**Figure 2**). Note that the “field on”  
38  
39 loops are not presented here, since electrostrictive effects and electrostatic interactions between  
40  
41 the cantilever and the back electrode can complicate the interpretation of the hysteresis loops  
42  
43 obtained. However, they are presented and discussed further below. Evidence is presented here for  
44  
45 FE hysteresis (**Figure 2d**) and 180° FE switching between two antiparallel polarization states (**Figure**  
46  
47 **2e**) is indicated for flakes from 100nm thick down to thicknesses of 14nm. Vertical DART-PFM  
48  
49 switching spectroscopy was also conducted on much-thinner individual flakes, as shown in **Figures**  
50  
51 **3a, b, c**. These vertical DART-PFM measurements demonstrate piezoelectricity in nano-structured  
52  
53 B5TFCO flakes with thickness of 8nm (which corresponds to 2 unit cells of B5TFCO) and diameter of  
54  
55 160nm. Note that this flake appears to have two domains (indicated by areas with a 180° phase shift  
56  
57  
58

64  
65

1 between them) and with a domain wall running approximately vertically down the center of the  
2 flake. The presence of different domain structures has previously been demonstrated<sup>[30]</sup> for  
3 nanodots of similar geometry but with irregularities in shape and strain. The multi-domain character  
4 may be helping to stabilize the piezoresponse at these smaller dimensions.  
5  
6

7  
8  
9 Ferroelectricity was investigated for this and other individual flakes: 4.2nm thick / 100 nm  
10 diameter (aspect ratio 24:1) and 2.4nm thick / 80nm diameter (aspect ratio 33:1), as demonstrated  
11 by the piezoresponse and phase vertical DART-PFM switching spectroscopy hysteresis loops (**Figure**  
12 **3d,e** respectively). 180° FE switching is observed in all cases. The smaller flake thicknesses  
13 correspond to one unit-cell and to just over half a unit cell of B5TFCO, respectively. Note that one  
14 edge of the 4.2 nm thick flake has overlapped on top of the 2.4 nm flake and is therefore somewhat  
15 tilted. These flakes were initially imaged in contact mode AFM (no AC bias) to obtain the  
16 topography images inset in **Figure 3d,e**. Following this, DART-PFM switching spectroscopy hysteresis  
17 loops were obtained. PFM imaging (i.e. scanning the PFM tip while applying an AC drive voltage) of  
18 the smaller flakes (4.2 nm and 2.4 nm in height) could not be obtained because the process caused  
19 physical damage. Large-scale surface damage at increased bias has previously been reported for PZT  
20 ( $\text{PbZr}_{0.52}\text{Ti}_{0.48}\text{O}_3$ ) nanodots.<sup>[31]</sup>

37 APMs are well-known FEs and ferroelectricity has been established for Co-substituted  
38  $\text{Bi}_5\text{Ti}_3\text{FeO}_{15}$  ceramics and thin film samples.<sup>[27, 32]</sup> However, the fact that ferroelectricity has been  
39 established for larger structures is not proof that ferroelectricity will exist at smaller dimensions. We  
40 now consider the results of the PFM experiments to ascertain if they support FE behavior,  
41 considering that other contributions (e.g. electrostatic effects, electrostrictive effects, surface  
42 electrochemical reactions, charge migration effects)<sup>[33]</sup> can affect the PFM signals. We note that the  
43 loops follow the typical counterclockwise behavior expected for standard FEs.<sup>[33]</sup> The piezoresponse  
44 versus applied voltage PFM loops for the B5TFCO flakes were performed in a pulsed DC mode which  
45 minimizes electrostatic and electrostrictive contributions to the signal<sup>[34]</sup>. However, measurement of  
46 loop evolution with  $V_{ac}$  (drive amplitude) is a necessary step to establish the validity of PFM

1 hysteresis measurements.<sup>[35]</sup> For most electromechanically active materials with dominant  
2 piezoelectric coupling and weak electrostrictive contributions, when below the coercive voltage of  
3 the material, the piezoresponse amplitude is directly proportional to  $V_{ac}$  while the piezoresponse  
4 phase is  $V_{ac}$  independent.<sup>[36], [33]</sup> Linearity of piezoresponse (pm) with drive amplitude ( $V_{ac}$ ) was  
5 verified for a flake of 76nm height and 579nm diameter at a constant DC bias of 15 V (**Figure S4**).

8  
9

### 11 **PFM Response Modelling**

12 An interesting aspect to the hysteresis loops observed from the exfoliated flakes and shown  
13 in **Figures 2** and **3** is their shape at high voltages. The piezoresponse is observed to increase at high  
14 voltage, rather than to saturate, as would be expected for a perfect switched FE. The shape is  
15 reproducible across the series of flake thicknesses and applies to both flake aggregates and single  
16 crystals. This type of loop shape has been reported before from a range of materials, including PFM  
17 data from thin films of e.g. BiFeO<sub>3</sub>,<sup>[37]</sup> strain-free SrTiO<sub>3</sub><sup>[38]</sup> and P/E loops from PVDF-TrFE films and  
18 composites with 5%BiFeO<sub>3</sub>-NaNbO<sub>3</sub> powders,<sup>[39]</sup> although hitherto it has not been explained. It is  
19 likely that the effect observed is due to the injection of charge from the electrodes into the FE after  
20 the switching of polarization in both positive and negative senses, creating a layer of trapped, but  
21 mobile, charge (electrons or holes) that increases the local polarization and thus the piezoresponse.  
22 However, when the field is removed the charge might be expected to leak away, and this is what we  
23 observe.  
24

39  
40  
41

42 To understand the detailed shape of the PFM loops (and, indeed the whole of the field-on,  
43 field-off response), we need to consider in detail how the PFM experiment is performed. Starting  
44 from zero applied field, a small AC voltage is applied to the PFM tip, and the piezoresponse is  
45 measured in individual time slots  $\Delta t$  (e.g.  $\Delta t=0.5\text{ms}$ ). N (say N=50) readings are taken at zero applied  
46 bias, giving a total field-off measurement time of  $\Delta t=N\cdot\Delta t$  (25ms in this example). This is the first  
47 “field-off” response measurement. A DC bias ( $V_1$ ) is applied for a time  $\Delta t$  (in this example for 25ms)  
48 and a further N (50) “field-on” response measurements are taken. The DC bias is removed and a  
49 further N (50) “field-off” response measurements taken. These are the “field-off” piezoresponse  
50

63  
64  
65

1 readings corresponding to  $V_1$ , with the readings being averaged over a pre-set number of the 50  
2 readings taken. This process is repeated with  $V_1$  increased (or decreased) by an amount  $\Delta V$ , to give  
3  
4 the full hysteresis loop. The parameters  $\Delta t$ ,  $N$  and  $\Delta V$  can all be varied within the PFM instrument  
5 parameters. To model the piezoresponse behavior in the presence of mobile charge injection and  
6  
7 leakage, consider how the charge will move into and out of the FE during the field-on and field-off  
8  
9 periods, taking account of the switching of the FE polarization through the loop cycle. To do this, we  
10  
11 use the approach of Pintilie and Alexe<sup>[40]</sup>, later modified by Fan et al.<sup>[41]</sup>, who considered the  
12  
13 thermionic emission of current into an insulator across a metal-insulator junction, including the  
14  
15 effects of FE polarization and charge trapping. The descriptions are based on a modified version of  
16  
17 the Schottky barrier model.  
18  
19  
20  
21  
22  
23  
24  
25  
26  
27  
28  
29

30 The energy bands at a Schottky contact between a metal and an insulator (or  
31 semiconductor) are illustrated as in **Figure 4a**<sup>[41]</sup>.  $\phi_B^0$  is Schottky barrier height set by the Fermi level  
32  
33 in the metal,  $V_{bi}$  is the height of the built-in potential barrier and  $w$  is the width of the Schottky  
34  
35 depletion region. In **Figure 4b** we see the description of the barrier in the presence of the FE  
36  
37 polarization  $P$ . The FE is assumed to have been poled by the application of a negative voltage to the  
38  
39 metal, so the FE polarization can be treated as a sheet of positive charge situated at a depth  $\delta$  below  
40  
41 the metal-FE interface. This is called “negatively poled” and denoted  $P \uparrow$  and changes (in this case  
42  
43 increases)  $V_{bi}$  to some value  $V'_{bi}$  and the  $\phi_B^0$  is increased to  $\phi_{App}$ . The converse poled case is shown  
44  
45 in **Figure 4c**. The layer defined by  $\delta$  is sometimes referred to as the “dead layer”. Fan et al.<sup>[41]</sup>  
46  
47 assume that charges injected into the FE become trapped and reside in the dead layer with a  
48  
49 volumetric density  $N_{Trapped}$  to give a total charge  $Q_{Trapped}$ , (in  $\text{Cm}^{-2}$ ) given by:  
50  
51

The following equations are derived by Fan et al.<sup>[41]</sup> They are very similar to the equations derived by Pintilie and Alexe<sup>[40]</sup> but include the effects of the charge trapped in the dead layer.

$$V'_{bi} = V_{bi} \mp \frac{P}{\epsilon_0 \epsilon_{st}} \delta \pm \frac{qN_{Trapped}}{2\epsilon_0 \epsilon_{st}} \delta^2 \quad (2)$$

$$V_{bi} = \phi_b^0 - \frac{k_B T}{q} \ln \left[ \frac{N_V}{p(T)} \right] \quad (3)$$

In the above,  $\epsilon_0$ = permittivity of free space;  $\epsilon_{st}$ =low frequency permittivity of FE,  $k_B$ =Boltzmann's Constant;  $N_V$ =Density of states for holes in the valence band;  $p(T)$ = Hole concentration at temperature  $T$ .

The depletion width is given by:

$$w = \left( \frac{2\epsilon_0 \epsilon_{st} (V + V'_{bi})}{qN_{eff}} \right)^{\frac{1}{2}} \quad (4)$$

Here,  $V$ =applied voltage and  $N_{eff}$ =effective charge density in the films.

The maximum field at the interface is given by:

$$E_m = \frac{qN_{eff}w}{\epsilon_0 \epsilon_{st}} \pm \frac{P}{\epsilon_0 \epsilon_{st}} \mp \frac{qN_{Trapped}}{2\epsilon_0 \epsilon_{st}} \delta \quad (5)$$

In equations (2) and (5), the lower signs apply to the case of a negatively poled FE where  $P \uparrow$  and the upper signs for the reverse case.

This can be put into a form that eliminates  $w$ :

$$E_m = \left[ \frac{2qN_{eff}(V + V'_{bi})}{\epsilon_0 \epsilon_{st}} \right]^{\frac{1}{2}} \pm \frac{P}{\epsilon_0 \epsilon_{st}} \mp \frac{qN_{Trapped}}{2\epsilon_0 \epsilon_{st}} \delta \quad (6)$$

The apparent barrier height is given by:

$$\phi_{App} = \phi_B^0 - \sqrt{\frac{qE_m}{4\pi\epsilon_0\epsilon_{opt}}} \quad (7)$$

Where  $\epsilon_{opt}$ =optical frequency permittivity of FE

In the presence of strong carrier recombination, Pintilie<sup>[40]</sup> quotes:

$$J = qN_V v_D \exp\left(\frac{-q\phi_{App}}{k_B T}\right) \quad (8)$$

Where  $v_D$  is the carrier diffusion velocity which is proportional to the carrier drift mobility  $\mu_D$ . This can be rewritten as:

$$J = qN_C \mu_D E_m \exp\left(\frac{-q\phi_{App}}{k_B T}\right) \quad (9)$$

Where  $N_C$  is the density of carriers available for the drift into the charge traps. This is likely to be mediated via a hopping process so that the current density is “bulk limited”, rather than being limited by thermionic emission into the FE from the electrodes.

Based on the previous observation that  $\mu_D$  is strongly dependent on temperature, we assume that  $\mu_D$  is determined by some sort of thermal activation process and an equation of the form:

$$\mu_D = \mu_D^0 \exp\left(\frac{A}{k_B T}\right) \quad (10)$$

To model the space charge contribution to the PFM response, we assume that during the “field-on” part of the PFM cycle, some space charge is injected into the sample, with a current as determined by the Schottky barrier model described above. This adds to the sheet polarization due to the FE polarization. During the “field-off” part of the cycle, the space charge will tend to leak away with a certain time constant that will depend on the electrical conductivity of the system, permittivity etc. This will give an exponential-decay function. We assume that in each part of the field-on cycle, the charge is injected to give a trapped charge:

$$Q_{Trapped} = J\Delta t \quad (11)$$

Where  $\Delta t$  = “field-on” time as defined above.

This will add to the total polarization  $P_T$  in the system, so that:

$$P_T = P + Q_{Trapped} \quad (12)$$

During a field-off cycle, the magnitude of the piezoelectric coefficient  $d_{eff}$  is then given in terms of the electrostrictive coefficient  $Q_{11}$  by:

$$d_{eff} = 2Q_{11}P_T\varepsilon_0\varepsilon_{st} \quad (13)$$

During a “field-on” cycle, the applied voltage induces a further polarization  $P_{ind}$ , which is given by:

$$P_{ind} = V\kappa\varepsilon_{eff}\varepsilon_0/t \quad (14)$$

Where  $\kappa$  is a variable introduced to allow for effects of FE thickness, tip geometry etc. on the induced polarization.

During the field-on cycles, the sign of  $P_{ind}$  is observed to be opposite to the sign of  $P_T$ .

$$d_{eff} = 2Q_{11}(P_T - P_{ind})\varepsilon_0\varepsilon_{st} \quad (15)$$

In making a calculation for  $d_{eff}$ , we also need to take account of the fact that the “dead-layers” at each FE-metal interface are non-FE, low permittivity materials. These place two capacitors in series with the active FE layer, which reduces the AC field across the FE, and hence the measured

$d_{eff}$ , by a factor  $F_{Red}$ :

$$F_{Red} = \left( \frac{\varepsilon_{st}}{\varepsilon_{opt}} \frac{1}{\left(\frac{t}{2\delta} - 1\right)} + 1 \right)^{-1} \quad (16)$$

We also need to take account of the way the trapped charge leaks away during both the field-on and field-off cycles. This accomplished by applying an exponential charge leakage term. To model the time structure, we split each field-on and field-off period into a number of N steps (e.g. 50). We assume that the injected current is constant throughout each step period. (This is an approximation as the current is affected to some extent by the number of trapped charges.) The  $N_{Trapped}$  (and hence the value of  $Q_{Trapped}$ ) at the end of each period  $\Delta t$  is calculated in the following way:

1. The  $N_{Trapped}$  is given a starting value for  $V=0$ , say  $N_{Trapped}^0$ . This is chosen to be equal to the value at the end of a complete cycle when the voltage again returns to zero. It is found that the result is not strongly dependent on the value chosen for  $N_{Trapped}^0$ .
2. During each section m of a field-on period, the value of  $N_{Trapped}$  is calculated as:

$$N_{Trapped}^m = \frac{J\Delta t}{q\delta} + N_{Trapped}^{m-1} \exp(-\gamma\Delta t) \quad (17)$$

Where  $\gamma$  is a decay constant and  $N_{Trapped}^{m-1}$  is the number of carriers trapped at the end of the previous period.  $J$  is calculated using equations (6) and (9) with the value of  $N_{Trapped}$  in equation (6) being set as the value of  $N_{Trapped}^{m-1}$ .

3. During each section  $m$  of a field-off period, the value of  $N_{Trapped}$  at the end of each section  $m$  is calculated as:

$$N_{Trapped}^m = N_{Trapped}^{m-1} \exp(-\gamma\Delta t) \quad (16)$$

The value of  $N_{Trapped}^m$  at the end of each period is used to calculate the trapped charge density from:

$$Q_{Trapped} = N_{Trapped}^m q\delta \quad (17)$$

This is then used in equations (12) to (15) to calculate  $d_{eff}$  throughout the field-on and field-off cycles.

In their modelling, Fan et al.<sup>[41]</sup> used a square hysteresis loop. Real FEs are almost-never so well-behaved, and in this model the values of the FE polarization as a function of field used in Equations (5) and (6) are derived using the semi-empirical tanh function described by Miller et al.<sup>[42]</sup> and Blom et al.<sup>[43]</sup> Here, the polarization  $P(E)$  is described as a function of the electric field  $E$  using:

$$P(E) = \varepsilon_0(\varepsilon_{opt} - 1)E + P_S \tanh\left[\frac{E \pm E_c}{2\alpha}\right] \quad (18)$$

Where  $P_S$ =Spontaneous Polarization,  $P_R$ =Remanent Polarization,  $E_c$ =Coercive Field and:

$$\alpha = E_c \left[ \ln \frac{1+\beta}{1-\beta} \right] \quad \beta = \frac{P_R}{P_S} \quad (19)$$

This produces a loop as illustrated in **Figure S4**. In this graph, the “positive going” arm of the loop takes the minus-sign in the tanh function in Equation (18), while the “negative going” arm of the loop takes the plus-sign. Loop shifts (either in the polarization or voltage axes) caused by in-built biases (charge or voltage asymmetries) are frequently observed in FE thin films (Refs). In this model we have allowed for the possibility of loop displacements in either the voltage or polarization axes by introducing the parameters  $P_{Shift}$  and  $V_{Shift}$ .

In our model, we use the following parameters for all the examples:

$N_V = N_C = 2 \times 10^{28} \text{m}^{-3}$ ;  $N_{eff} = 4 \times 10^{28} \text{m}^{-3}$   $p(300) = 5 \times 10^{24} \text{m}^{-3}$ ;  $\Phi_B^0 = 1.3 \text{eV}$  (these are similar to the values used by Fan et al. for PZT films<sup>[41]</sup>).  $N_{trapped}(t = 0) = 10^{21} \text{m}^{-3}$

The low frequency permittivities  $\epsilon_{st}$  have been measured for a range of Aurivillius oxides, and the values are quite similar. These include 140 for  $\text{CaBi}_4\text{Ti}_4\text{O}_{15}$ <sup>[44]</sup>, and 160 for hot-forged  $\text{Bi}_4\text{Ti}_3\text{O}_{12}$ <sup>[45]</sup>. A value of  $\epsilon_{st}=140$  has been used here. A refractive index of 2.7 in  $\text{Bi}_4\text{Ti}_3\text{O}_{12}$  has been measured by Cummins<sup>[46]</sup>, corresponding to an optical permittivity of 7.3. We have used a value of  $\epsilon_{opt}=6.5$  in this model. The value of  $\delta$  (dead layer thickness) was fixed at 0.035nm, similar to the value derived by Dawber et al.<sup>[47]</sup> in their modelling of dead layer thicknesses and polarization field correction in FE switching in PVDF, and the value fits well with our observations.

The parameters  $V_C$  (coercive voltage),  $V_{Shift}$ ,  $P_S$ ,  $\Delta P_R = P_S - P_R$ ,  $P_{Shift}$ ,  $\mu_D$  (carrier drift mobility),  $\gamma$  (charge decay constant),  $\epsilon_{eff}$  (effective permittivity) and  $Q_{11}$  (electrostrictive coefficient) were fitted parameters. These were fitted by a process of least-squares (minimizing  $r^2 = \sum(d_{obs} - d_{calc})^2 / \sum(d_{obs}^2)$ ) over the full field-on and field-off data for measurements of  $d_{eff}$ . Two data points were ignored on each side of the voltage switching transient, so 46 data points were fitted in each field-on or field-off period, and the models were fitted over one-and-one-half full voltage cycles so nearly 10,000 data points were taken for each fitting. Note that the first half-cycle was ignored as this serves to polarize the point on the flake in a particular direction. It was observed that  $Q_{11} = 2(\pm 0.1) \times 10^{-2} \text{m}^4 \text{C}^{-2}$ . This is in the middle of the range observed for FE perovskite titanates<sup>[48]</sup>.

FE and butterfly loops were plotted by taking the average of the last 10  $d_{eff}$  values in each field-off period, for both the observed and modelled values and plotting them against the applied voltage value in the immediately-preceding field-on period.

The results of the fitting for a 30nm thick flake are shown in **Figure 6**. It can be seen that the model describes the behaviour of  $d_{eff}$  well, in both the time-structure and around the butterfly and

1 hysteresis loops. The parameters derived from the fitting process, and the  $r^2$  values for each fit, are  
2 given in **Table S1**.  
3

4  
5 **Figure 7** shows comparisons between the observed and modelled PFM piezoresponse data  
6 for flakes of 2.4, 4.2, 8 and 14nm thickness, together with the time-structure PFM response for the  
7 2.4nm flake, including an example where we have “zoomed-in” on part of the time structure. The  
8 agreement between the modelled and observed data is very good for both the PFM loops and the  
9 field-on and field-off time structures. If we look in detail at the materials parameters used to model  
10 the data, we find that the low frequency ( $\epsilon_{st}$ ) and optical ( $\epsilon_{opt}$ ) permittivities used (140 and 6.5) are  
11 in excellent agreement with parameters for similar materials in the literature:  $\epsilon_{st} = 140$  for  
12  $\text{CaBi}_4\text{Ti}_4\text{O}_{15}$ <sup>[44]</sup>, and 160 for hot-forged  $\text{Bi}_4\text{Ti}_3\text{O}_{12}$ <sup>[45]</sup> and  $\epsilon_{opt} = 7.5$  in  $\text{Bi}_4\text{Ti}_3\text{O}_{12}$  (Cummins<sup>[46]</sup>). The value  
13 of  $\delta$  (dead layer thickness) used in our model was fixed at 0.035nm. This is similar to the value  
14 derived by Dawber et al.<sup>[47]</sup> in their modelling of dead layer thicknesses and polarization field  
15 correction in FE switching in PVDF. We observed that  $Q_{11} = 2(\pm 0.1) \times 10^{-2} \text{m}^4\text{C}^{-2}$ . This is in the middle  
16 of the range observed for FE perovskite titanates<sup>[48]</sup>. Based on an out-of-plane spontaneous  
17 polarization of  $0.04 \text{Cm}^{-2}$  observed by Takenaka<sup>[45]</sup> in hot-forged  $\text{Bi}_4\text{Ti}_3\text{O}_{12}$ ,  $\epsilon_{st} = 160$  and a  $Q_{11} = 2 \times 10^{-2}$   
18  $\text{m}^4\text{C}^{-2}$  we calculate for that material an out-of-plane piezoelectric coefficient  $d$  of  $2.3 \text{pmV}^{-1}$ . This is  
19 in excellent agreement with the values obtained at zero applied voltage for the 14nm thick flake  
20 shown in **Figure 4d**. The thinner flakes show somewhat smaller values of  $d$ . The parameters  
21 extracted from the fitting of the model to the observed data on all the flakes studies are given in  
22 **Table S1**. The values of  $P_S$  are not strongly dependent on flake thickness, showing a good deal of  
23 scatter, which is what would be expected if some of the flakes were slightly canted out of the plane.  
24 We observe an average value of  $0.04(\pm 0.02) \text{Cm}^{-2}$ . The mean value is in very good agreement with  
25 the value observed for  $\text{Bi}_4\text{Ti}_3\text{O}_{12}$ , as reported above, although this may simply be a coincidence, as  
26 discussed below.

1 We do not see a strongly systematic variation of either the drift mobility (average  
2  $\mu_D=1.4 \times 10^{-6} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ ) or the charge decay constant (average  $\gamma = 18 \text{ s}^{-1}$ ) with flake thickness (see **Table**  
3  
4 **S1**). The dependence of these parameters on temperature, and the comparison of flakes with thin  
5  
6 films, will be the subject of a further publication.  
7

8  
9 **Figure 7a** shows the variation of the coercive field  $E_C$  with thickness. (Here, we have taken  
10  
11 the mean values of  $E_C$  for all the 33nm thickness measurements conducted at different maximum  
12  
13 applied voltages  $V_{Max}$ ). Empirically,  $E_C$  increases with decreasing thickness of the FE material<sup>[47]</sup>. As  
14  
15 explained by Ducharme et al.<sup>[49]</sup> the extrinsic coercive field observed in FEs is caused by localized  
16  
17 nucleations of domains with reversed polarization. Defects are often the source of domain walls, and  
18  
19 thicker flakes have a higher probability of containing defects, meaning that thicker flakes are more  
20  
21 easily polarized than thinner flakes. As first observed by Kay and Dunn in triglycine sulfate<sup>[50]</sup>, the  
22  
23 scaling of  $E_C$  with thickness ( $t$ ) follows the semi-empirical scaling law:  $E_C \propto t^{-\frac{2}{3}}$ . In the case of our  
24  
25 data, if we simply plot ( $E_C$ ) vs  $t$  (using a log-log scale) we observe an empirical relationship  $E_C \propto t^{-1}$   
26  
27 (the “uncorrected” data in **Figure 7a**). However, if we apply a depolarization correction to the field  
28  
29 data, as discussed by Dawber et al.<sup>[47]</sup>, such that:  
30  
31

32  
33  
34  $E_C(\text{Corrected}) = E_C / (t + 2\delta\epsilon_{st})$  where  $t$  is the thickness of the relevant flake, and  $\delta$  the  
35  
36 thickness of the dead layer (using the model values of  $\delta=0.035 \text{ nm}$  and  $\epsilon_{st}=140$ ), then we get the  
37  
38 “corrected” plot in **Figure 7a**, which produces an exponent of -0.7, close to the value of 0.66  
39  
40 expected from the Kay and Dunn law.  
41  
42  
43  
44  
45  
46

47 Finally, we should comment on the observed values of  $\kappa$  and the way these are observed to  
48  
49 vary with flake thickness. In a perfect system, we would expect  $\kappa=1$ , so that the polarization induced  
50  
51 by the applied field is directly proportional to the field and a constant value of  $\epsilon_{st}$  for all flake  
52  
53 thicknesses, but this is not the case here. The observed values of  $\kappa$  are plotted as a function of flake  
54  
55 thickness in **Figure 7b**. Empirically, we observe that  $\kappa$  is proportional to flake thickness over the full  
56  
57 range of flake thicknesses, although there is a fair degree of scatter in the measurements. There are  
58  
59  
60  
61  
62  
63  
64  
65

1 a range of reasons as to why this might be the case. The effect of field concentration at the PFM tip  
2 and the way that interacts with the flake thickness may be one cause of non-linearity and the effects  
3  
4 of damage in the oxide at low thicknesses may be another. This is an area for further study.  
5  
6

## 7 **Discussion and Outlook**

8  
9 We have reported here the fabrication and characterization by various probe microscopies  
10  
11 of exfoliated APM B5TFCO nanoflakes. These are either stacked together as multi-flakes or  
12  
13 dispersed individually with flake thicknesses ranging from 120nm to 2.4nm. PFM imaging has  
14  
15 demonstrated piezoelectricity in both lateral and vertical directions with higher piezoresponses in  
16  
17 the lateral ( $11\text{pmV}^{-1}$ ) compared with the vertical ( $2\text{-}3\text{pmV}^{-1}$ ), as expected for APMs with the major  
18  
19 polarization vector along the  $a$ -axis. Local PFM switching loops were generated for the nano-sized  
20  
21 flakes. The details of the PFM response, including the time-structure in both field-on and field-off  
22  
23 states, has been accurately described with a model using charge injection through a Schottky barrier  
24  
25 at the electrode-FE oxide interface, in association with charge storage in (and time-dependent  
26  
27 leakage from) a surface layer, where the charge injection is affected by the magnitude and sign of  
28  
29 the FE polarization. The parameters derived from this model such as permittivities, electrostrictive  
30  
31 coefficients, spontaneous polarization magnitudes etc. are all in excellent agreement with values for  
32  
33 similar materials taken from the literature. Based on the parameters derived from fitting this model  
34  
35 to the data, the coercive field ( $E_C$ ) scales with thickness ( $t$ ), following the semi-empirical scaling law:  
36  
37

38  
39  
40  
41  
42  $E_C \propto t^{-\frac{2}{3}}$ . It is believed that the balance of evidence obtained from the PFM measurements

43  
44 indicates that room temperature ferroelectricity can exist, and can be switched, in nano-structured  
45  
46 B5TFCO flakes as thin as 4.2 and 2.4 nm. The observation of multi-domain structures within single,  
47  
48 unpoled nanoflakes which have not undergone PFM-driven switching is supporting evidence for the  
49  
50 existence of ferroelectricity in these very thin flakes. The observation of out-of-plane FE switching in  
51  
52 such thin flakes for an APM with  $m=4$  is very interesting. Normally, we would not expect to see any  
53  
54 component of  $P_S$  out of the basal plane of an APM structure for which  $m$  is even.<sup>[28, 51]</sup> Clearly, we  
55  
56 see a switchable component of  $P_S$  in our measurements. The most-likely explanation is that the  
57  
58  
59  
60  
61  
62  
63  
64  
65

1 flakes are not lying perfectly parallel to the underlying substrate surface, in which case we would  
2 reasonable expect to be able to switch a component of the in-plane polarization. A simple estimate  
3 shows that for an in-plane  $P_S$  of  $0.4\text{Cm}^{-2}$  (as expected for most APM FEs), a flake would only need to  
4 be sitting at an angle ( $\Phi$ ) of  $<6^\circ$  to give an out-of-plane component of  $\approx 0.04\text{Cm}^{-2}$ , the average value  
5 observed in this work. However, the smallest measured values of out-of-plane  $P_S$  in Table S1 would  
6 correspond to values of  $\Phi \approx 2.5^\circ$  and the largest  $\Phi \approx 10^\circ$ . Nevertheless, the observed values of the  
7 out-of-plane  $P_S$  component observed in this work are remarkably consistent from grain to grain, and  
8 across the different grain thicknesses, and very similar to the value observed for  $\text{Bi}_4\text{Ti}_3\text{O}_{12}$ , so the  
9 intriguing possibility remains that we are seeing an intrinsic out-of-plane component for  $P_S$ , which  
10 would mean that the symmetry is not as expected ( $A2_1am$ ),<sup>[52]</sup> but something lower. This possibility  
11 requires further work to resolve. It should be noted that a thickness of 4.2nm corresponds closely to  
12 the thickness which would be expected for a single unit cell, while 2.4nm is a thickness  
13 corresponding to half the unit cell, plus one  $\text{Bi}_2\text{O}_2$  layer, or slightly more than half a unit-cell of  
14 B5TFCO (see **Figure 1**). The thinnest flake would thus appear to be four perovskite blocks in  
15 thickness, sandwiched between two  $\text{Bi}_2\text{O}_2$  layers. We believe that these are the first PFM  
16 measurements on exfoliated APMs. The results are a noteworthy contribution to the fundamental  
17 research of both ultra-thin piezoelectric and FE materials and also demonstrate for the first time that  
18 wide band-gap oxide FEs can be added to the growing class of 2D materials. This is an important  
19 conclusion, as it offers the prospect of incorporating the wide range of useful FE properties, vis: a  
20 large switchable, built-in spontaneous polarization, piezoelectricity, pyroelectricity etc. into future  
21 electronic devices exploiting 2D materials. In addition, we believe that the model for PFM response  
22 presented here will be a useful tool for those working with this technique as a means for  
23 characterizing FE behavior in thin materials.

## 56 **Methods**

1 Highly-oriented polycrystalline ceramics of  $\text{Bi}_5\text{Fe}_{0.5}\text{Co}_{0.5}\text{Ti}_3\text{O}_{15}$  prepared via molten salt synthesis<sup>[27]</sup>  
2 were used as the starting material for the liquid exfoliation process.  $\text{Bi}_5\text{Ti}_3\text{Fe}_{0.5}\text{Co}_{0.5}\text{O}_{15}$  powder was  
3 dispersed in an aqueous solution of the surfactant sodium cholate ( $0.1 \text{ mgml}^{-1}$  concentration) using  
4 an ultrasonic processor (Sonics VX-750) operating at 75% amplitude for 90 mins. The dispersions  
5 were left to settle for 72 hours. The top 50% was then decanted into 2 glass vials and centrifuged  
6 (Hettick Mickro 22R) at 500rpm for 30 mins to remove any remaining unexfoliated material.  
7 Decantation was carried out by pipetting off the top 50% of each dispersion in a single glass vial. Thin  
8 films were made by vacuum filtration immediately after centrifugation. Dispersions were filtered  
9 through a nitrocellulose membrane (pore size 25mm) and the deposited films were washed with  
10 400ml of Millipore water to remove surfactant. Films were dried for 20 minutes at  $50^\circ\text{C}$  before  
11 transfer onto Ti coated  $\text{SiO}_2$ . Films were wetted with isopropyl alcohol and pressed against the  
12 substrate. The cellulose filter was removed by treatment with acetone vapor and subsequent  
13 acetone liquid baths. Films were annealed at  $800^\circ\text{C}$  to remove any remaining surfactant. Flake  
14 morphology was analyzed by scanning electron microscopy (SEM) (Zeiss Ultra Plus SEM and FEI  
15 DualBeam Helios NanoLab 600i). Cross-sections of the flakes were prepared for micro-structural  
16 analysis using a FEI DualBeam Helios NanoLab 600i SEM/FIB (focused ion beam) (final thinning at  
17 93pA 30kV, final polish 2kV 28pA). Samples were gold-coated to prevent charging. Micro-structural  
18 analysis was performed on the B5TFCO flakes using HR-TEM (high resolution transmission electron  
19 microscopy; Jeol 2100 transmission electron microscope; 200kV; double tilt holder). Elemental  
20 mapping was performed using STEM-EDX (Scanning Transmission Electron Microscopy-Energy  
21 Dispersive X-Ray Diffraction; Helios Nanolab STEM - medium spot size, x-ray generation area 10-30  
22 nm in diameter, 100-300 nm lamella thickness). A commercial atomic force microscope (AFM)  
23 (MFP-3D™, Asylum Research) was used for topography mapping of the films. Diameter and height  
24 values reported in this manuscript were determined by topographical imaging. Electromechanical  
25 responses of the films were measured by PFM using an Asylum Research MFP-3D™ AFM in contact  
26 mode, equipped with a HVA220 Amplifier for PFM using Single Frequency (drive frequency of 20

1 kHz) PFM. The angular torsion of the cantilever as it oscillates was monitored in lateral  
2 measurements, which were conducted in a similar manner to the vertical measurements except the  
3  
4 'InFast' option was programmed to 'Lateral'. The Dual AC Resonance Tracking Piezoresponse Force  
5  
6 Microscopy (DART-PFM)<sup>[29]</sup> mode was used to boost the vertical piezo signal. In this mode, the PFM  
7  
8 signal is measured at the tip-sample contact resonance frequency, where the drive frequencies are  
9  
10 adjusted as the probe scans over the changing sample topography in order to reduce topographical  
11  
12 cross-talk. Olympus AC240TM Electrilevers, Ti/Pt coated silicon cantilevers (Al reflex coated, 70kHz  
13  
14 resonant frequency, ~320kHz contact resonance frequency) were used for PFM and topography  
15  
16 imaging. The Inverse Optical Lever Sensitivity of the cantilevers was calibrated according to the  
17  
18 MFP-3D Procedural Operation 'Manualette', the system inherent background was determined using  
19  
20 a non-piezoelectric silicon wafer and the PFM was then calibrated using  $\alpha$ -quartz as a reference  
21  
22 sample. Vertical hysteresis loop measurements were obtained at fixed tip positions on the surface of  
23  
24 the particles by switching spectroscopy PFM (SS-PFM)<sup>[53]</sup> using a triangular step waveform  
25  
26 (comprised of pulse DC (direct current) bias voltage of 15-35V and an AC (alternating current) drive  
27  
28 voltage ( $V_{ac}$ ) of 5.5V). The waveform was cycled twice at a frequency of 0.3Hz with 55-83 AC steps  
29  
30 per waveform. Hysteresis loops taken on a particular flake location were repeated at least three  
31  
32 times whereupon repeatable results were obtained.

## Author Contributions

1  
2 R.W.W. proposed the idea of exfoliating APMs into nano-structured flakes and exploring their FE  
3  
4 properties. M.P. and A.J.B. synthesized the B5TFCO ceramic sample. R.J.S. and J.N.C. developed the  
5  
6 liquid exfoliation method and fabricated the nano-structured B5TFCO flakes. M.S. performed HR-  
7  
8 SEM, HR-TEM and STEM-EDX characterization of the B5TFCO flakes. L.K. performed the PFM  
9  
10 SEM, HR-TEM and STEM-EDX characterization of the B5TFCO flakes. L.K. performed the PFM  
11  
12 measurements. R.W.W. devised the model for the PFM response and undertook the modelling of  
13  
14 the data. L.K. and R.W.W. wrote the first draft of the manuscript. The final version of the manuscript  
15  
16 was written through contributions of all authors. All authors have given approval to the final version  
17  
18 of the manuscript.

# Figures

**Figure 1:** Schematic diagram of the B5TFCO APM structure, viewed approximately along [110], illustrating the main structural features and the relevant unit cell dimensions.

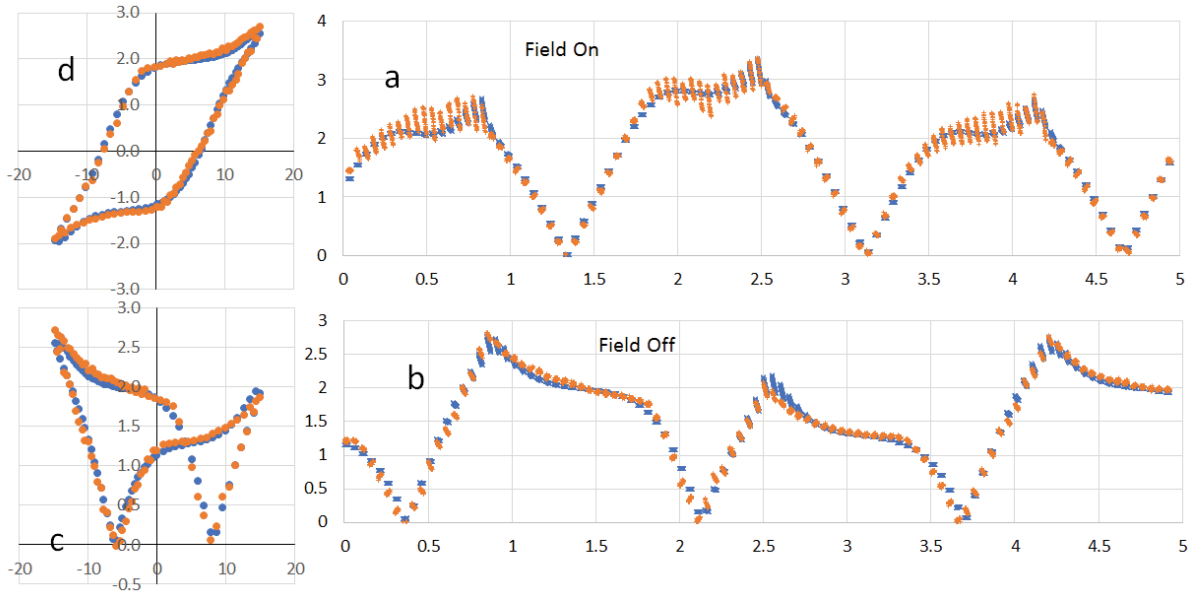

**Figure 2.** Representative **a.** topography, **b.** vertical DART-PFM amplitude and **c.** vertical DART-PFM phase images of a single 15nm-high flake of exfoliated B5TFCO. Vertical DART-PFM switching spectroscopy **h** piezoresponse and **i** phase loops of exfoliated B5TFCO nanoflakes at room temperature after removal of an applied DC bias.

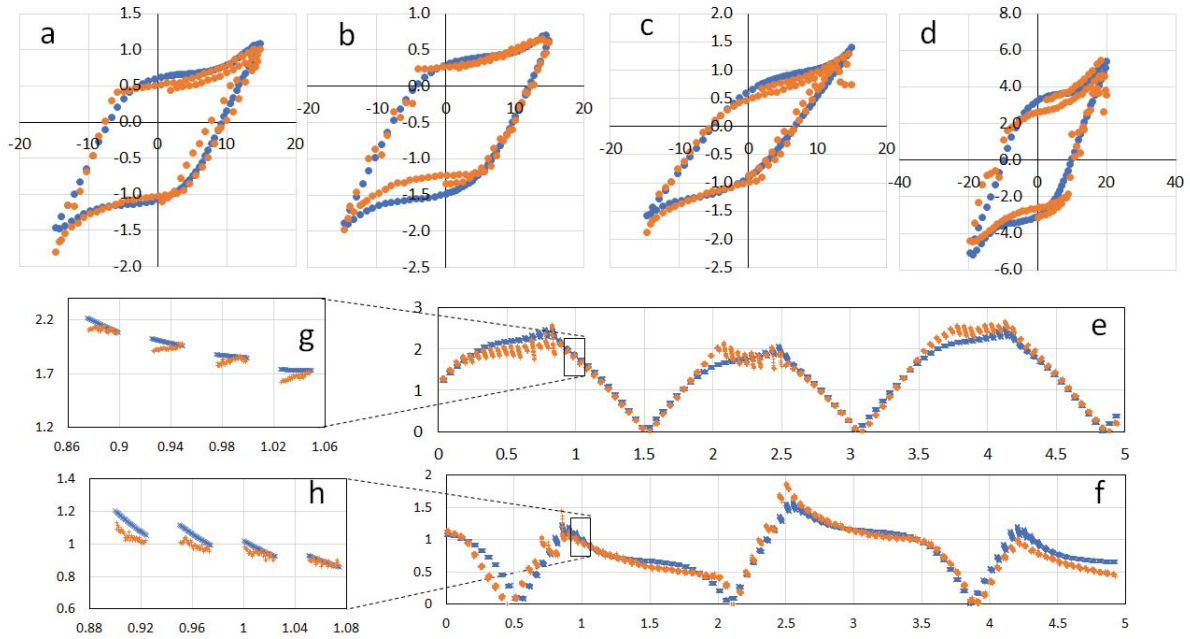

**Figure 3.** Representative **a** topography, **b** vertical DART-PFM amplitude and **c** vertical DART-PFM phase images of an individual exfoliated 8nm thick B5TFCO flake. Vertical DART-PFM switching spectroscopy **d** piezoresponse and **e** phase loops of individual exfoliated B5TFCO flakes at room temperature after removal of an applied DC bias. The topography of flakes with height 2.4 nm and 4.2 nm are shown in the inset in **d** and the topography of flake with height 8nm is shown in the inset in **e**.

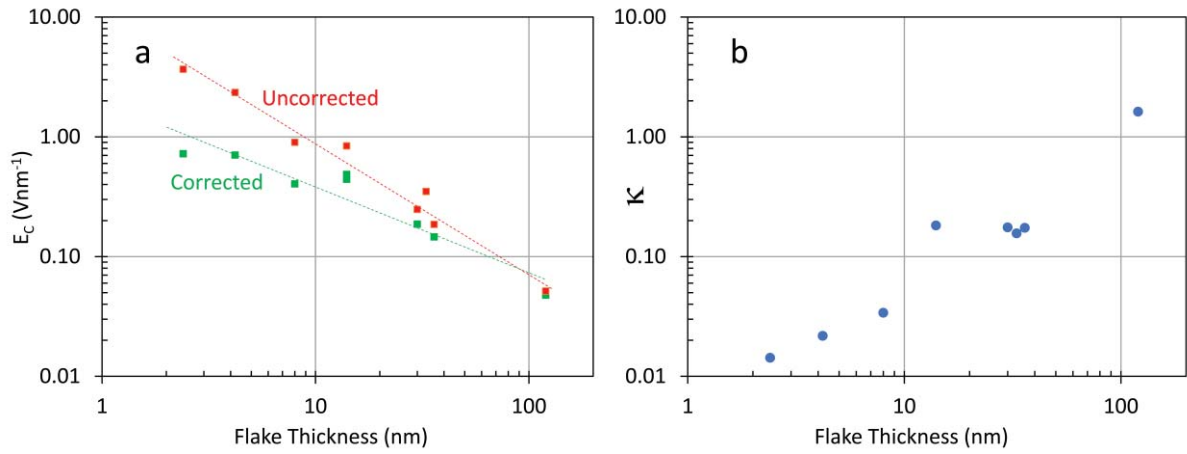

**Figure 4.** Energy band diagrams of a Schottky diode in **a** virgin (without polarization and trapped charges), **b** negatively poled and **c** positively poled states (redrawn with permission from Fan et al. 2017, American Physical Society<sup>[41]</sup>).

**Figure 5.** Results of fitting the parameters as discussed in the text for a 30nm thick B5TFCO flake. This shows **a** Field-on and **b** Field-off time responses in  $\text{pmV}^{-1}$ . In each case the horizontal axes are plotted in seconds. **c** Butterfly and **d** Hysteresis loops in  $\text{pmV}^{-1}$  plotted vs applied voltage. In each case, the observed data is plotted in orange and the modelled data in blue.

**Figure 6.** Comparison of measured and modelled PFM piezoresponse hysteresis loops for **a** 2.4nm, **b** 4.2nm, **c** 8nm and **d** 14nm exfoliated B5TFCO flakes. In each case the piezoresponse (vertical axes) is measured in  $\text{pmV}^{-1}$  and the applied voltage (horizontal axes) in volts. Figures **3 e** and **f** show respectively the field-on and field-off time structures of the piezoresponse signals (in  $\text{pmV}^{-1}$ ) for the 2.4nm flake. Figures **3 g** and **h** show respectively magnified sections of the field-on and field-off time structures of the piezoresponse signals (in  $\text{pmV}^{-1}$ ) for the 2.4nm flake. The horizontal axes are plotted in seconds. In each case, the observed data is plotted in orange and the model data is plotted in blue.

**Figure 7. a** Log-log plots of the uncorrected and corrected coercive fields vs flake thickness and **b** Log-log plot of the variable  $k$  vs flake thickness as derived from the fits of the model to the measured piezoresponse data.

# Ferroelectric Behavior in Exfoliated 2D Aurivillius Oxide Flakes of Sub-Unit Cell Thickness

## Supporting Information

Figure S1. Supporting Information: Representative top-view HRSEM image of exfoliated B5TFCO flakes.

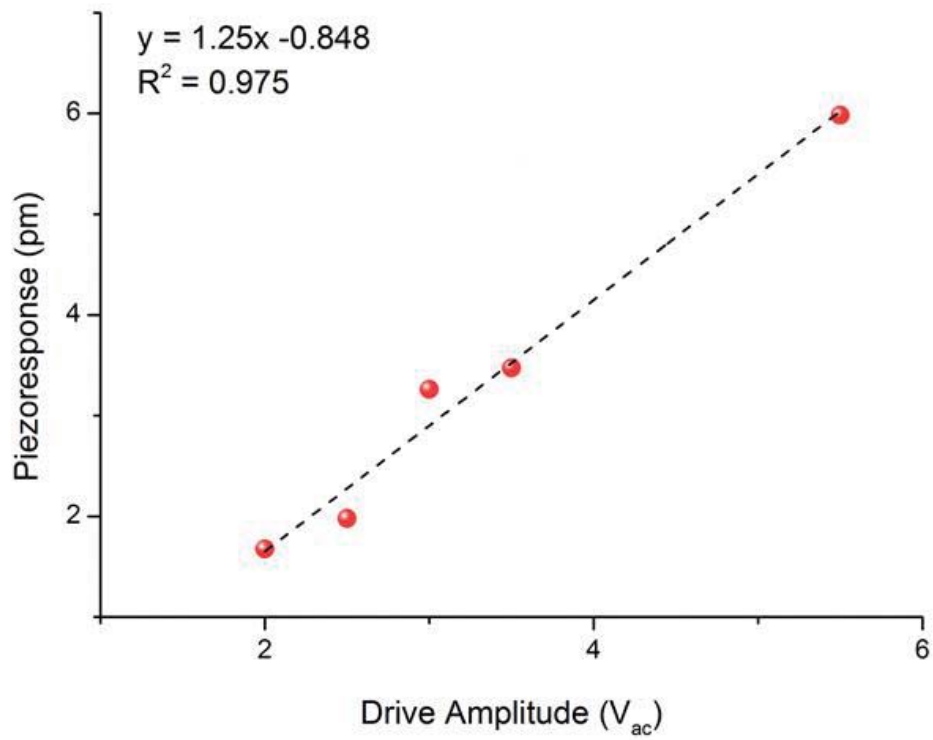

**Figure S2.** Cross-sectional TEM images of exfoliated B5TFCO flakes. HRTEM of a larger horizontal cluster of multi-flakes (maximum thickness of 80nm and diameter of 230nm) **a** and HRTEM of a smaller vertical multi-flake stack (maximum thickness of 65nm and diameter of 80nm) **b**.

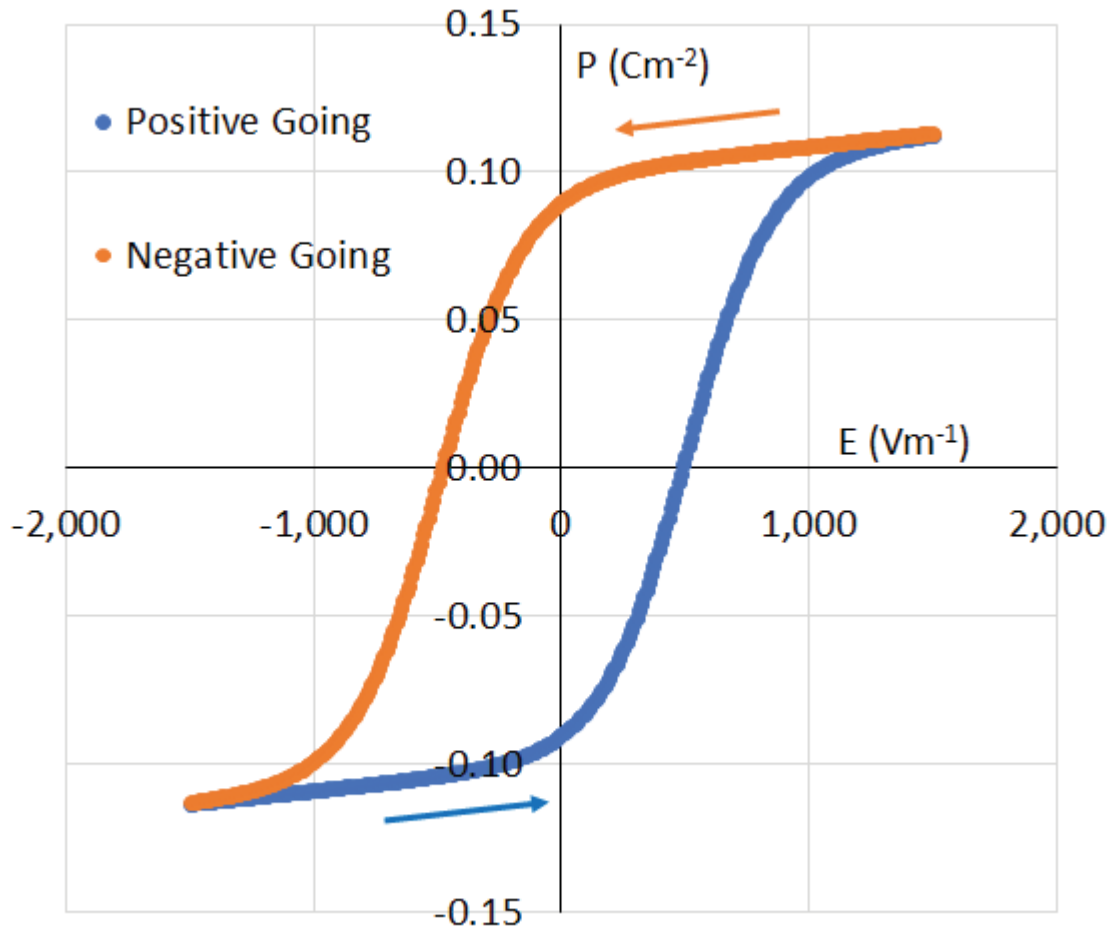

**Figure S3.** Representative **a.** topography, **b.** lateral single frequency PFM amplitude, **e.** lateral single frequency PFM phase, **c.** vertical single frequency PFM amplitude and **f.** vertical single frequency PFM phase **d.** vertical DART-PFM amplitude and **g.** vertical DART-PFM phase images of a multi-flake cluster of exfoliated B5TFCO.

**Figure S4.** Piezoresponse as measured by vertical DART-PFM switching spectroscopy as a function of drive voltage (2.0 to 5.5V) at a constant DC bias of 15V. Note that the piezoresponse has not been normalized to  $\text{pmV}^{-1}$ , it has been displayed in picometers (pm) to allow for the change in piezoresponse as a function of voltage to be demonstrated.

## PFM Response Modelling

**Figure S5.** Model of ferroelectric hysteresis based on the function shown in Equation (S18) and (S19).

( $P_S=0.1\text{Cm}^{-2}$ ,  $P_R=0.09\text{Cm}^{-2}$ ,  $E_c=500\text{Vm}^{-1}$ ,  $\epsilon_{opt}=2$ ).
