Abstract

There are many geoscience problems for which constraining histories of uplift or subsidence of Earth's surface is of direct or indirect importance, for example reconstructing tectonics, mantle convection, geomorphology, sedimentary and chemical flux, biodiversity, glacio-eustasy and climate change. The least equivocal constraints on timing and amplitude of vertical motions on geological timescales come from the distribution of rock formed in shallow marine environments. However, obtaining enough observations at sufficiently large spatial and temporal scales ($\sim 100 - 10,000$ km, $\sim 1 - 100$ Ma) to constrain histories of regional topographic evolution remains challenging. To address this issue we adapted modern inventories of paleobiological and paleoenvironmental data to generate a new compilation of $> 24,000$ spot measurements of uplift on all continents and numerous ocean islands. Uncertainties associated with paleobathymetry, post-deposition compaction and glacio-eustasy are assessed. The compilation provides self-consistent, and, in places, high-resolution (< 100 km length-scale, < 1 Ma), measurements of Cretaceous to Recent (post-deposition) net uplift across significant tracts of most continents. To illustrate how the database can be used, records from western North America and eastern South America are combined with geophysical observations (e.g., free-air gravity, shear and Pn-wave tomography) and simple isostatic calculations to determine origins of topography. We explore how lithospheric thinning and mantle thermal anomalies may generate uplift of the observed wavelengths and amplitudes. The results emphasize the importance of large inventories of paleobiological data for understanding histories of tectonic and mantle convective processes, and consequently, landscapes, climate and the environment.

INTRODUCTION

Vertical motions of Earth's surface are used to inform almost all branches of the Earth Sciences. They are used to understand, for example, growth of mountain ranges, deep Earth rheology, natural hazards, histories of mantle convection, glacio-eustasy and sedimentary basin formation (e.g., *Ziegler et al.*, 1985; *White and McKenzie*, 1988; *Molnar and England*, 1990; *Densmore and Hovius*, 2000; *Copley and McKenzie*, 2007; *Hoggard et al.*, 2016). Understanding how topography grows and decays is a fundamental geologic concern but also important for understanding chemical fluxes, the distribution of natural resources and biodiversity. For example, the elevation, history and erosion of topography are crucial components for understanding chemical fluxes to the oceans, weathering, atmospheric and oceanic circulation and biotic distributions (e.g., *Raymo and Ruddiman*, 1992; *Anderson and Anderson*, 2010; *Herman et al.*, 2013; *Perrigo et al.*, 2019). As such, topographic evolution plays a central role in understanding climate change throughout geological time (*Mitrovica et al.*, 2020). Despite more than 100 years of study, defining and understanding histories of topographic growth and decay on geologic timescales remain important topics of research (e.g., *Davis*, 1899; *Suess*, 1906; *Hack*, 1975; *Ziegler et al.*, 1985; *Sahagian*, 1987; *Mitrovica et al.*, 1989; *McDonough and Cross*, 1991; *Rowley*, 2013). In this study we adapt existing paleobiological databases to produce 24,372 individual measurements of net uplift since Cretaceous times. These measurements are used to consider how lithospheric and sub-plate processes generate observed timings, amplitudes, and wavelengths of uplift.

Previous work

In general, subsidence is better preserved in the geological record than uplift because erosion tends to remove the rock record we wish to measure. Uplift and associated landscape evolution is often estimated indirectly using proxies. A consequence of uplift is increased potential energy, which results in the erosion, transport and deposition of clastic material. As such, histories of solid sedimentary efflux at continental margins have been qualitatively and quantitatively related to patterns of uplift in most continents (e.g., *Walford and White*, 2005; *Guillocheau et al.*, 2012; *Galloway et al.*, 2011; *Lodhia et al.*, 2018; *Fernandes et al.*, 2019). Thermal and compaction histories of rocks can be linked to uplift via inferred histories of denudation (e.g., thermochronometry, vitrinite reflectance, sonic velocities; see *Walford and White*, 2005; *Anderson and Anderson*, 2010). Radiometric and biostratigraphic techniques can be used to date eroded surfaces, which in many places can be related to changes in base-level generated by, say, uplift (e.g., *Bierman and Steig*, 1996; *Aciego et al.*, 2007; *Finnegan et al.*, 2014; *Stucky de Quay et al.*, 2019). Isotopic data, basalt morphology and paleobotany are also used to constrain elevation of topography via functions (lapse rates) that correlate, for example, temperature, or isotopic compositions, with elevation (e.g., *Gregory and Chase*, 1992; *Garzione et al.*, 2000; *Ghosh et al.*, 2006; *Sahagian and Proussevitch*, 2007; *Chamberlain et al.*, 2012). Some of these observations have recently been shown to be self-consistent with predictions of uplift, denudation and sedimentary flux generated by inverting continental-scale drainage networks (see e.g., *Fernandes et al.*, 2019).

A suite of geodetic and geologic observations exists to directly measure uplift and subsidence at a range of scales. For example, contemporary measurements of vertical motion from geodetic data (e.g., InSAR, GPS) have improved understanding of active tectonics and associated seismic hazards (e.g., *Reilinger et al.*, 2010; *Elliott et al.*, 2016). Uplifted, radiometrically dated Holocene terraces and historical records at tide gauges are crucial constraints on the viscoelastic response of the lithosphere and mantle to unloading (e.g., *Lambeck et al.*, 1998; *Watts*, 2001; *Pedoja et al.*, 2014). The least equivocal constraints on the history of uplift on timescales of tens of thousands to millions of years come from dated marine rock. Pioneering work, by for example *Ziegler et al.* (1985) and *Sahagian* (1987), showed that Cretaceous marine sedimentary strata across North America and Africa provide evidence for kilometer-scale, long wavelength, uplift during the last 100 million years (see also *Holmes*, 1965; *Burke and Gunnell*, 2008). Using these observations to determine uplift histories relies on accurate identification of marine lithologies and paleoenvironments. A general challenge with using these important inventories to constrain histories of, say, sub-plate support is their sparsity. In contrast, stratigraphy along passive margins and the relationship between age and depth of the oceans provide well resolved estimates of modern and ancient sub-plate support (see e.g., *Czarnota et al.*, 2013; *Hoggard et al.*, 2016; *Lodhia et al.*, 2018; *Morris et al.*, 2020).

Recent studies measuring vertical motions of continental topography on geologic timescales have similarly focused on mapping the difference between modern and paleo-elevations of dated sea-level markers (e.g., *Bétard*, 2010; *Dorsey et al.*, 2011; *Peulvast and Bétard*, 2015; *Bessin et al.*, 2017). These studies understandably tend to focus on regional scales (e.g. tens to hundreds of kilometers). Recently, the paleobiology community has assembled large inventories of paleontological data from across the globe to address large-scale paleobiological questions (e.g., paleodb.org; geobiodiversity.com). For example, genera in the Paleobiology Database (PBDB) include 24,372 records of Cretaceous to Recent marine fossil assemblages from all continents and many ocean islands. In this study we make use of that inventory and coincident elevation measurements to constrain uplift at > 24,000 localities, which includes estimates for all continents and many ocean islands (Figure 1).

This paper has three parts. First, the simple methodology for measuring net uplift is explained using an example from western North America. The scheme used to assess the veracity of records in the PBDB, in particular the approach to identify extraneous records is explained. Uncertainties generated by paleobathymetry, post-deposition compaction and denudation, and sea level change are estimated. Second, amplitude, wavelength and timing of vertical motions for two case studies — the Western Interior of North America and Borborema Province, northeastern Brazil — are given. Finally, an example is provided of how net uplift measured using

the PBDB can be used to give insight into the geologic evolution of continents. The uplift measurements are combined with geophysical observations (e.g., free-air gravity, shear and Pn-wave tomography) and simple isostatic calculations to elucidate the mechanisms responsible for generating the present-day elevation of continental topography.

CALCULATION OF VERTICAL MOTIONS

In many cases the current elevation of fossil assemblages on continents provides a reasonably good (minimum) constraint on net uplift since deposition. This result is a consequence of paleo-water depths in epicontinental seaways typically being small (less than a few hundred meters), post-deposition compaction tending to reduce elevations of uplifted marine rock, and far-field glacio-eustatic sea-level changes being of small amplitude (<200 m) compared to many (kilometer-scale) uplift estimates. However, in some places (e.g., where there is significant structural relief) these uncertainties can be important. Therefore the following sections describe procedures to calculate uplift and uncertainties from PBDB records. In its simplest form net uplift, U , is calculated as

$$U = E + B - S + \Delta C, \quad (1)$$

where E is present-day elevation of the marine fossil assemblage, B is paleobathymetry, S is sea-level at the time of deposition and ΔC is a correction that accounts for post-depositional compaction of sediments. Maximum and minimum estimates of uplift can be simply calculated using extreme uncertainties in elevation, paleobathymetry, sea level and compaction (e.g., $U_{max} = E_{max} + B_{max} - S_{min} + \Delta C$; $U_{min} = E_{min} + B_{min} - S_{max}$). If these quantities are measured with uncorrelated and random uncertainties (i.e. δE , δB , δS , $\delta \Delta C$) then uplift uncertainties, δU , can be calculated by quadrature, i.e. $\delta U = [(\delta E)^2 + (\delta B)^2 + (\delta S)^2 + (\delta \Delta C)^2]^{1/2}$. Similarly, uncertainties in average uplift rate, $U' = U/A$ where A is sample age (with associated uncertainty δA), can be expressed as $\delta U' = |U'|[(\delta E/E)^2 + (\delta B/B)^2 + (\delta S/S)^2 + (\delta \Delta C/\Delta C)^2 + (\delta A/A)^2]^{1/2}$. We note that we calculate surface uplift and that associated rock uplift can be significantly higher in denuded regions (e.g., *England and Molnar, 1990*).

The following sections describe the methodology used to calculate uplift with the aid of an example from the Prairie Canyon Member of the Mancos Shale, western Colorado (Figure 2; *Kass, 1999*). The key fossil assemblages at this locality are preserved within the siltstone part of this member and include shark teeth, *Bacculites* ammonites, inoceramid bivalves and mosasaur skull fragments. This stratigraphy was interpreted as Campanian in age based on the fossil assemblage and regional chronostratigraphic correlations (*Obradovich and Cobban, 1975*; *Merewether and McKinney, 2015*).

Paleobiology Database (PBDB)

Fossil occurrences were retrieved from the PBDB on 8th July 2019 using the following filters: Maximum Age = 100.5 Ma, Minimum Age = 0 Ma (Cenomanian to Recent). The total number of records (fossils) downloaded was 580,637. This inventory contains information about age, location, stratigraphic origin (i.e. formation, unit, member), lithology, paleoenvironment and tectonic setting at the time of deposition and references to original source material. The inventory also identifies fossil assemblages, i.e., fossils that are located at the same site and stratigraphic level, which are usually obtained from cited studies.

The records obtained from the PBDB required modification prior to generating uplift constraints. The three most important modifications were as follows. First, all fossils identified as non-marine (i.e. ‘terrestrial’), or those with no information about paleoenvironment, were removed from the database. Assemblages containing genera that do not necessarily represent marine conditions were also removed (e.g., birds that fly inland). For example, four records from inland Australia that document assemblages containing only species of the Pelecanidae family (pelicans) were removed. The total number of remaining marine fossil assemblages is 24,372. Each assemblage will subsequently be referred to as a point, and used to calculate uplift. Second,

in general most points are accurately located. However, a small number are assigned incorrect locations in the database and must be corrected manually (e.g., whales off the coast of Hawaii were incorrectly assigned locations in Australia and Brazil). Locations of all key assemblages shown in this paper were checked and < 1% required manual intervention. Finally, qualitative paleoenvironmental information is converted into quantitative estimates of paleobathymetry. Paleoenvironmental information is recorded in the PBDB as, for example, ‘*shallow subtidal*’, ‘*estuary/bay*’, ‘*slope/basin*’, as is information about the tectonic setting, for example, ‘*passive margin*’, ‘*foreland basin*’. The PBDB identifies 37 different paleoenvironments and 14 tectonic settings, accompanied by descriptions (See Figure 3; Table 1 for names and descriptions). The approach used to generate quantitative estimates of paleobathymetry is described in detail in the following section. Finally, points with poorly constrained paleobathymetry were corrected, where possible, using the methodology outlined below.

Bathymetric model

A variety of schemes exist to convert paleoenvironment descriptors into quantitative estimates of paleo-water depth (see Supplementary Material; e.g., *Sahagian et al.*, 1996; *Immenhauser*, 2009). We used Immenhauser’s (2009) scheme as it tends to yield conservative estimates of paleo-water depth, especially for shallow water environments (see Figure 3, Table 1). For example, we define water depths for ‘*very shallow marine*’ as 0 – 50 m, ‘*shallow marine*’ as 0 – 100 m, ‘*shelf*’ as 0 – 250 m, ‘*upper bathyal*’ as 250 – 500 m, ‘*middle bathyal*’ as 500 – 2000 m, and ‘*lower bathyal*’ as 2000 – 4000 m. We compared paleobathymetries calculated using this approach to 13 other schemes (see Table 2 in Supplementary Material). We find that there is generally close agreement between approaches. The most significant discrepancies are for shallow water environments (< 200 m), for which the Immenhauser conversion scheme tends to be more conservative (i.e. has the greatest range of water depths).

An important concern is whether the paleoenvironment of a given fossil assemblage reported in the PBDB is consistent with other paleoenvironmental interpretations for the same unit. To address this question we have benchmarked 14 randomly chosen points from North America, Africa and Europe against independent references (see Supplementary Material Table 3). For example, PBDB entry number 23,864 is an Eocene assemblage from the Bashi Member of the Hatchetigbee Bluff Formation of Alabama, US. It is reported in the PBDB as a sandstone deposited within a peri-reef or sub-reef environment by *Palmer and Brann* (1965). These deposits probably formed within a shelf environment in the vicinity of a reef but do not contain direct evidence of in-situ reef growth. Using our preferred conversion scheme they yield a paleo-water depth of 1–250 m (Table 1). An independent paleoenvironmental classification of the Bashi-Hatchetigbee Bluff deposits, which crops out as an East-West band in northern Alabama and Georgia, is given by *Gibson and Bybell* (1981). Based on foraminifera assemblages and sedimentology (e.g., the occurrence of shelly glauconitic silt and very fine grained sand, commonly including a thin sequence of laminated silt and clay at the top), they identify the depositional facies as inner shelf (inner to middle neritic, i.e. < 150 m; *Olson and Leckie*, 2003). The other benchmarks are similarly consistent.

Table 1: Bathymetric model, descriptions of environments as given in the PBDB documentation, and attributed paleo-bathymetric ranges.

No.	Environment	Description	min B [m]	max B [m]
1	Basin Reef	Deep water reef growing close to basin floor.	500	1000
2	Basinal (carbonate)	On slope, basinal oozes that are predominantly carbonate, deep-sea.	500	3000
3	Basinal (siliciclastic)	On slope, terrigenous mud, deep-sea.	500	4000
4	Basinal (siliceous)	On slope, cherty deposits, deep-sea.	500	4000
5	Carbonate indet.	All carbonate deposits where environment of deposition cannot be determined.	0	3000

6	Coastal indet.	Coastal environment where a specific non-deltaic setting cannot be identified.	0	50
7	Deep Subtidal	Deposited between normal wave base and typical storm wave base.	15	50
8	Deep Subtidal Ramp	Ramp between normal and storm weather wave base.	15	50
9	Deep Subtidal Shelf	On flat shelf or platform between normal and storm weather wave base.	15	50
10	Deep-water indet.	Unspecified deep sea.	250	4000
11	Delta Front	Marine delta portion, more open marine, with significant fresh water input.	1	15
12	Estuary/Bay	Shallow water with fresh water influence; perpendicular to shore, including wave base.	0	15
13	Foreshore	Coastal. Sandstone with gently dipping planar cross lamination with minimal bioturbation.	0	1
14	Interdistributary Bay	Delta with marine influence, at sea level and may contain marine to brackish water faunas.	0	2
15	Intraplatform Reef	Reef in shallow-water portion of a platform, but not near its margin.	0	100
16	Lagoonal/Restricted Shallow Subtidal	Up to a few meters of water depth, hyposaline, restricted water movement.	0	2
17	Lagoonal	Up to a few meters of water depth, hypersaline. Shallow marine with fresh water; influence parallel to shore, including wave base. Carbonate or siliciclastic.	0	5
18	Marginal Marine indet.	Shallow setting, dominated by wave, river and tidal processes. Depositional settings include delta, beach, barrier island, estuarine, lagoonal, tidal flat.	0	15
19	Marine indet.	All marine siliciclastic deposits.	0	4000
20	Offshore	Below typical storm wave base, although can be affected by exceptionally strong storms. On the continental slope. Shale with storm sand beds, pervasive bioturbation of <i>Cruziana</i> .	50	250
21	Offshore indet.	Below typical storm wave base, although can be affected by exceptionally strong storms. On the continental slope. Unknown platform geometry.	50	250
22	Offshore Ramp	Carbonate platforms which have a very low gradient depositional slope (commonly less than 0.1) from a shallow-water shoreline or lagoon to a basin floor.	50	250
23	Offshore Shelf	The term shelf is more widely used in geologic context for any broad, gently-sloping surface, clastic or carbonate, which has a break in slope in deeper water.	50	250
24	Open Shallow Subtidal	Up to a few meters of water depth, normal marine salinities.	1	15
25	Paralic indet.	Shallow marine, cannot distinguish between lagoon or estuary, including wave base.	0	15
26	Peri-reef or Sub-reef	Carbonate deposits in the vicinity of a reef, however not containing in-situ reef growth.	1	250
27	Peritidal	Shallow marine. Includes supratidal and intertidal settings and may be characterized in arid climates by evaporite minerals, dolomite, and desiccation cracks, but in humid climates by bioturbated mudstones with fenestral pores.	0	2

28	Platform/Shelf-margin Reef	Located on a carbonate platform margin.	0	250
29	Prodelta	Deeper marine delta portion, mud-dominated, difficult to distinguish from offshore deposits.	15	100
30	Reef, Buildup or Bioherm	Reef of uncertain geographical position relative to the shore or continental shelf margin.	0	250
31	Sand Shoal	Strong wave or tidal currents and consequently displays large-scale trough cross-stratification of well-sorted grainstone, but may also display seaward-inclined laminae where it is developed in a foreshore setting.	0	15
32	Shallow Subtidal indet.	Up to a few meters of water depth, salinity undetermined.	1	15
33	Shoreface	Coastal. Sandstone with large-scale trough cross-bedding and <i>Skolithos</i> . On weak wave climate, may be highly bioturbated with wave-ripple laminae.	1	50
34	Slope	Slumps, slides, debrites, turbidites.	250	4000
35	Slope/Ramp Reef	Growing on a shelf slope or carbonate ramp.	50	250
36	Submarine Fans	Deep water depositional systems generated by turbidity currents, often associated with a delta system.	1500	4000
37	Transition Zone/Lower Shoreface	Coastal. Mudstone and hummocky cross-stratified sandstone, mixed <i>Skolithos</i> – <i>Cruziana</i> .	15	70

At face value the largest paleo-water depth uncertainties are associated with 11,447 assemblages recorded as forming in indeterminate marine environments (i.e. ‘*marine indet.*’). However, many records contain comments that provide additional information that can be used to improve estimates of paleo-water depth. These ‘*geologic comments*’ are often excerpts from publications from which the database entries were made. This additional information was also used to ensure consistency between the database and original publications. For example, the point numbered 10,119 is a fossil assemblage from the Gram Formation, Denmark (Tortonian; 11.6 – 7.2 Ma). It was recorded in the database as ‘*marine indet.*’ and no indication of tectonic setting was given. However, the ‘*geologic comments*’ noted that “[the] Gram Formation was deposited in a marine environment at a depth between 50 and 100 m, as indicated by the marine flora associated with terrestrial material, foraminifera and the marine fauna”. These more precise estimates were used to modify the database entry. All entries corrected in this way are labeled ‘b’ in the inventory of uplift constraints (see Supplementary Material). If the ‘*geologic comments*’ did not provide additional information on the source of the data (e.g., the original paper) then other publications were consulted. These points are labeled ‘c’ in the data tables provided and associated citations are given in Supplementary Material. Any points that were not corrected using either of these two methodologies are labeled ‘a’. Of the 12,765 points that have accurate paleo-water depth records > 90% have minimum paleo-water depth estimates of 50 m or less, and maximum paleo-water depth estimates of 250 m or less (see Supplementary Material).

As another example, consider the fossil assemblage shown in Figure 2. The PBDB entry is consistent with the original publication, which places the assemblage near Cedaredge, Colorado, on the easternmost portion of the Book Cliffs and states that it is contained within the “Mancos B” (the Prairie Canyon) Member of the Mancos Shale (Cole *et al.*, 1997). The depositional environment is interpreted as offshore marine based on sedimentary architecture and fossil assemblage (mosasaur, shark teeth, ammonites and bivalves). This interpretation is consistent with that of Hampson (2010) who examined the sedimentology of distal portions of the Prairie Canyon Member in western Colorado. Using our preferred conversion scheme (Table 1) the paleo-water depth range for this assemblage is 150 ± 100 m (see Figure 2). In the following sections we examine two other potentially significant sources of error: sea-level and compaction.

Sea-level

Global changes in sea-level are challenging to constrain accurately on geological timescales. Many previous attempts have made use of two techniques. The first is identifying anomalous subsidence patterns from backstripped stratigraphy in regions with supposedly well understood tectonic histories (e.g., rifting and cooling of passive margins; *Watts and Steckler*, 1979). The second correlates stratigraphy from supposedly stable, or well understood, continental margins or interiors (e.g., *Vail et al.*, 1977). *Bessin et al.* (2017) presented a compilation of global sea-level curves produced using a suite of different methodologies (coastal onlap analysis, continental flooding, backstripping, ocean floor age-depth-area and isotope proxies; *Haq et al.*, 1987; *Haq and Al-Qahtani*, 2005; *Scotese and Golonka*, 1992; *Smith et al.*, 1994; *Miller*, 2005; *Kominz et al.*, 2008; *Müller et al.*, 2008; *Miller et al.*, 2011; *Rowley*, 2013). The compilation shows significant discrepancies between estimates of eustasy (100 – 200 m for some stages). These discrepancies are not surprising given that many estimates of glacio-eustasy are based on regional datasets in places where the stability (or predictability) of continental vertical motions is assumed. The role of mantle convection and complex hydrodynamic processes in modifying the vertical motions of supposedly stable continents and sea level is generally poorly understood on geological timescales but important (e.g., ocean syphoning: migration of water caused by surface deflections; *Mitrovica and Milne*, 2002; *Moucha et al.*, 2008a; *Flament et al.*, 2013; *Austermann et al.*, 2017). Amplitudes of global sea-level change are estimated to vary by as much as 200 m, whilst mantle-driven processes can produce changes in vertical motions of similar or greater amplitudes, and comparable timescales (*Miller*, 2005; *Lovell*, 2010). For example, backstripping of stratigraphy along passive margins combined with upper mantle shear wave tomographic models indicate that sub-plate support can generate up to ~ 1 km of uplift or subsidence at $\sim 10 - 10,000$ km wavelengths, on timescales of 1 – 100 Ma (e.g., *Czarnota et al.*, 2013; *Flament et al.*, 2013; *Lodhia et al.*, 2018; *Morris et al.*, 2020).

A pragmatic way to assess the impact of sea-level on calculated uplift is to use the range of values given for each stage in the compilation of *Bessin et al.* (2017). The extrema for each stage are used to define sea-level uncertainties, δS , and uplift is corrected by the mean value. Present-day sea-level is used as the reference frame for all measurements and paleo-sea level uncertainties are between -99 m and $+264$ m (see Supplementary Material).

Compaction correction

Post-deposition compaction of strata means that measurements of net uplift from elevations of fossil assemblages are minima (Figure 2). Correcting for compaction is not necessary for sedimentary rock that satisfies two criteria. First, they were deposited directly upon rock that will not compact significantly (e.g., crystalline basement; previously compacted rock). Second, they were not subsequently buried. However, many of the fossil assemblages within the database are contained within stratigraphy from sedimentary basins that accumulated significant stratal thicknesses before and after their deposition. Therefore a strategy for correcting for compaction is required.

The compaction correction, ΔC , is calculated by decompacting the thickness of underlying sedimentary rock, C_c , by removing overlying rock of thickness D . Porosity is parameterized using the well-known formulation by *Athy* (1930)

$$\phi(z) = \phi_o \exp\left(-\frac{z}{\lambda}\right), \quad (2)$$

where ϕ_o and λ are initial porosity and compaction wavelength, respectively, z is depth. Assuming that the solid fraction remains constant during compaction, the decompacted thickness is given by

$$\int_D^{D+C_c} [1 - \phi(z)] dz = \int_0^{C_d} [1 - \phi(z)] dz, \quad (3)$$

where D is the amount of denudation, C_c and C_d are compacted and decompacted sedimentary layer thicknesses, respectively. Substitution with Equation 2 and solving the integral gives

$$C_d = C_c + \phi_o \lambda \left[\exp\left(-\frac{D + C_c}{\lambda}\right) - \exp\left(-\frac{D}{\lambda}\right) + 1 - \exp\left(-\frac{C_d}{\lambda}\right) \right]. \quad (4)$$

C_d is solved iteratively for each layer using the Newton-Raphson method. The resulting compaction correction is $\Delta C = C_d - C_c$.

Compaction parameter values can be obtained from well data, for example, from direct measurements of porosity or via indirect means (e.g., the relationship between velocity and porosity; *Wyllie et al.*, 1956). Values of ϕ_o and λ can range from 0.25 – 0.7 and 1.4 – 3.7 km, respectively, in siliciclastic sediments, and 0.4 – 0.8 and 1.2 – 6.0 km in carbonates (*Magara*, 1980; *Sclater and Christie*, 1980; *Goldhammer*, 1997). Notwithstanding these constraints, estimates of C_c and D are usually minima because we cannot constrain how much of the sedimentary pile has been lost by erosion. For simplicity we have not applied this correction to the full database and explore compaction corrections on a case-by-case basis.

Figure 4 shows an example of applying a compaction correction to the test case in western North America. This fossil assemblage was deposited within the Piceance basin, which contains thick Cambrian to Pliocene sedimentary rock (*Johnson*, 1992). The stratigraphy consists of predominantly siliciclastic deposits (sandstones and shales; *UUPA Team*, 2003). The exact value of C_c depends on whether all Mesozoic sedimentary rock or only Cretaceous deposits ought to be decompacted ($C_{c1} = 1.4$ km and $C_{c2} = 2.7$ km, respectively; Figure 4; *Hintze and Kowallis*, 2009). Existence of a regional Lower Cretaceous unconformity throughout the Western Interior Basin suggests Early and Mid-Mesozoic rocks of the western Cordillera were compacted and partly eroded during Sevier orogenesis (e.g., *Bjerrum and Dorsey*, 1995; *Heller and Paola*, 1989). We therefore initially assume that they were not compacted by deposition of Cretaceous to Recent stratigraphy. Instead, we start by assuming that only Cretaceous sedimentary rock was affected by compaction, i.e. $C_c = 1.4$ km. Thickness of denuded rock, D , can be tentatively estimated from preserved thicknesses of sedimentary rock in adjacent non-eroded sections or neighboring basins of similar stratigraphy. This correction ought to be applied on a case-by-case basis because lateral changes in facies or structural variations can affect thickness estimates. D ranges from 0.8 – 2.9 km for this example (e.g., *Hintze and Kowallis*, 2009). Published porosity-depth data from wells in the adjacent Uinta Basin, which contain similar stratigraphy, have best-fit values of $\phi_o = 0.25$ and $\lambda = 3.0$ km (*Chapman et al.*, 1984). These compaction parameters, combined with the range of values of C_c and D , result in a compaction correction (additional uplift) of 0.08 – 0.31 km for the example shown in Figure 4.

Elevation

Locations in the PBDB are typically reported with an accuracy of at least 0.01° (~ 1 km at the equator). However, present-day elevation of each fossil assemblage is not usually provided. Instead it was extracted from digital elevation data. Elevations were extracted from the ETOPO1 digital elevation model, which has a grid spacing of one arc minute (~ 1.85 km) and sea-level as the vertical datum (*Amante and Eakins*, 2009). Other datums, such as mean high water, and mean low water, typically differ by less than the vertical accuracy of ETOPO1, which is of order 10 meters. We note that ETOPO1 was generated using weighted means from the SRTM30 data set (horizontal resolution ~ 30 m) and the GLOBAL digital elevation model, which was used to fill in gaps (*Amante and Eakins*, 2009). Higher resolution digital elevation data (e.g., ASTER, TanDEM-X) could also be used to extract information about elevation. For the PBDB points located in western North America and the Borborema Province, elevations from ETOPO1 differ from SRTM30 by < 60 m, which is significantly less than nearly all paleo-water depth uncertainties. The present-day elevation of our example from western North America is 1.90 km (Figure 2).

GLOBAL PATTERNS OF UPLIFT

Figure 5 shows the inventory of global uplift measurements calculated by combining present-day elevation, paleo-water depth and sea-level (Equation 1). Compaction corrections were not included for simplicity, as such, Figure 5 shows minimum net uplift. The collection of uplift measurements is particularly dense along the coastlines of most continents, as well as in western North America, Europe, Japan and New Zealand. Figure 5b–e shows examples of cross sections in places where the density of the inventory is such that uplift at

large length scales ($\sim 100 - 1000$ km) can be constrained. For example, a reasonably densely sampled transect can be constructed from northernmost North America to the southern tip of South America (Figure 5b). This transect includes the Yukon Plateau, Rocky Mountains, Mexican Highlands, the Andes, Altiplano, and Patagonia. A prominent feature of this transect is the > 2000 km wide post-Cretaceous domal swell centered on the Colorado Plateau in western North America. Patterns of uplift in the Andes and Altiplano contain shorter wavelength (< 500 km) relatively large, kilometer-scale, changes in net uplift. Transects through the southern Appalachian Mountains, North America, indicate that the topography there has been uplifted and tilted by ~ 300 m during the last ~ 40 Ma. These results are a consequence of careful biostratigraphic mapping by *Kirkland* (1996), *Keller et al.* (2002), *Sulser et al.* (2010) and many others. Citations to primary literature for all points are included in the data tables provided as Supplementary Material.

The inventory contains important, albeit sparse, measurements of uplift from within continental interiors. In northwest Africa the distribution of nearshore continental, marginal marine, and open marine fossils record the existence of a Cretaceous–Paleogene trans-Saharan seaway extending from the Gulf of Guinea, across Mali and Nigeria, to the present-day Mediterranean (e.g., *Berggren*, 1974; *Tintant et al.*, 2001; *Tapanila et al.*, 2008; *Boyden*, 2011; *O’Leary et al.*, 2019). Figures 5c–d show ~ 300 m of net uplift across western Africa, and ~ 600 m of post-Paleocene differential uplift of the Tibesti dome. Figure 5e shows 2 km of post-Oligocene uplift of the Caucasus Mountains and uplift measurements atop the Urals and the west Siberian Plain.

In eastern Australia, fossils from the shallow-marine Mackunda Formation, deposited during the final marine regression within the Eromanga basin, show a tilt of ~ 200 m with a wavelength of ~ 200 km. These observations complement those generated from correlation and backstripping of well data (*Gallagher and Lambeck*, 1989). Figure 5 contains many other examples of useful spot measurements of uplift, especially across South America and Eurasia. We examine two case studies in more detail: Western North America and the Borborema Province, Brazil.

Western North America

Cretaceous flooding of western North America resulted in widespread deposition and preservation of marine rock within the continental interior (Figure 6; e.g., *Sloss*, 1963; *Cross and Piliger*, 1978). Extensive exploration in the region has generated a well-constrained and generally accepted chronostratigraphy, as well as a large number of sedimentological and paleoenvironmental studies (*Obradovich and Cobban*, 1975; *Roberts and Kirschbaum*, 1995; *Johnson et al.*, 2002; *Gani et al.*, 2015; *Merewether and McKinney*, 2015).

Paleobathymetric estimates from the PBDB broadly agree with independent values. For example, they are consistent with local water-depth maxima estimated using the height of clinoforms (40 m, *Plint et al.*, 2009), planktonic to benthic foraminifera ratios (500 m, *Eicher*, 1969) and numerical simulation of oceanic circulation (100–400 m, *Ericksen and Slingerland*, 1990; *Dean et al.*, 2019). *Arthur and Sageman* (2004) correlated depositional environments, lithofacies and water depths in modern marine settings to infer maximum water depths of 200–300 m across most of the Cretaceous seaway, with local maxima of 1000 m. These values and smoothly varying paleowater-depth estimates indicate that a modern analogue is the Hudson Bay, a large, ~ 1000 km-wide seaway that has an undulated bottom in most parts and a mean water depth of ~ 150 m (*GEBCO; Stewart and Lockhart*, 2006).

The distribution of Cretaceous marine rocks within western North America today defines a domal swell centered on the Colorado Plateau (Figure 6d). Maximum uplift along the mountain belt increases to the south, from ~ 1.5 km in the Northern and Canadian Rockies (Figure 6e), to 2 – 2.5 km in the Middle Rockies (Figure 6f). The Southern Rocky Mountains and Colorado Plateau are foci of maximum post-Cretaceous net uplift (2.5–3 km; Figure 6g). Towards the east post-Cretaceous uplift decreases to ~ 0.5 km in the Great Plains where easternmost Cretaceous marine rocks are recorded. Previous studies of tilting or epeirogenic vertical motions in this region have made use of reconstructed Cretaceous sedimentary isopachs (*Cross and Piliger*, 1978; *Sahagian*, 1987; *Mitrovica et al.*, 1989). The new PBDB measurements provide additional direct constraints on uplift, including patterns of post-Cretaceous tilting across most of western North America.

These isopach maps can be used to assess the importance of compaction of Cretaceous sediments in affecting calculated uplift (e.g., *Cross and Pilger, 1978; Mitrovica et al., 1989; Roberts and Kirschbaum, 1995*). Reconstructed Upper Albian to Santonian isopachs indicate that up to 4 km of sedimentary rock in foreland basins formed as a result of loading by the Sevier orogen. Foci of thick sedimentary rock are in north-central Utah, southern Wyoming and southeast Idaho. Elsewhere, for example in eastern Colorado, eastern Wyoming, central Montana and New Mexico, mapped thicknesses are less than 500 m. Campanian to Maastrichtian isopachs record a different pattern of sedimentation. The thickest isopachs (2–3 km) are centered on eastern Wyoming and western Colorado. Thicknesses of less than 500 m are mapped eastwards of central North Dakota, South Dakota, Nebraska and Kansas. These observations suggest that the maximum sediment thickness that could have been compacted, C_c , is ~ 6 km (in northeast Utah/southeast Wyoming), decreasing to zero towards the easternmost extent of the basin (e.g., eastern Minnesota).

Maximum denudation, D , can be approximated using the thickness of Cenozoic sedimentary rock preserved within the Laramide intermontane basins (e.g., *Hintze and Kowallis, 2009*). For example, the Uinta Basin, Utah, contains up to 5.9 km of post-Cretaceous sedimentary rock, which we regard as a conservative (maximum) estimate of the amount of material denuded from other parts of western North America. Apatite fission track analyses of Late Cretaceous sedimentary rock, from outcrops within the Rocky Mountains, provide further evidence of $\sim 4 - 6$ km of denudation since the deposition of Cretaceous marine rock (e.g., *Herman et al., 2013*). By taking into account the range of possible ϕ_o and λ values the compaction correction is a maximum of 0.24–2.5 km centered on the Southern Rocky Mountains. For easternmost points, which sit directly above basement, their compaction correction is zero (*Dyman et al., 1994*). Assuming an average $\phi_o = 0.5$ and $\lambda = 3.6$ km the compaction correction would amplify the differential rock uplift between the Great Plains and Southern Rocky Mountains by ~ 1.3 km.

There are a suite of additional uplift and denudation constraints that can be brought to bear to understand the evolution of North American topography. For example, *Fernandes et al. (2019)* synthesized a suite of observations including stable isotopes, palynology, radiometrically dated incision, thermochronology and additional stratigraphic observations. They used a subset of uplift measurements generated from the PBDB and stratigraphic observations to test the results of a continent-wide inversion of drainage patterns. The inverse methodology uses families of drainage networks to recover smooth spatio-temporal uplift rate histories using a calibrated stream power erosional model (e.g., *Roberts et al., 2012*). That approach provides a means to fill in gaps between spot measurements of post-Cretaceous uplift.

Borborema Province, northeast Brazil

The second example is from northeastern Brazil, which includes the Borborema Province and Cretaceous rift basins. Figure 7 shows the spatial and temporal distribution of PBDB points, interpreted paleo-water depths and calculated uplift for the region. The broad domal swell of the region, with a diameter of 900–1000 km and amplitude of 700 m, is illustrated in the cross-sections shown (Figure 7e-f). Calculated post-Aptian net uplift is > 700 m.

The key constraint on large-scale uplift of this region is the presence of late Aptian-Cenomanian shallow marine deposits of the Romulado Formation at 700–900 m elevation within the Araripe basin (Figure 7a). A fossil assemblage from this deposit is recorded in the PBDB and geologic mapping shows that this unit crops out as a thin band close to the top of the Araripe Plateau (Figure 7a). The Romulado Formation, which is part of the Santana Group, forms a 3–5 m thick, shallowly dipping, black shale that is well known for excellent fossil preservation (e.g., *Martill, 1988*). Marine microfossils recovered in the well 2-AP-1-CE (dinoflagellate cysts, ostracodes and foraminifera), and a fossil-bearing layer towards the top of the formation containing Cretaceous gastropods, bivalves and echinoderms provides evidence of lagoonal and estuarine environments during a Cretaceous marine transgression (*Arai and Coimbra, 1990; Coimbra et al., 2002; Prado et al., 2016; Pereira et al., 2016*). Sedimentological evidence for marine depositional environments, including tide-dominated coastal facies and storm-dominated shelf sedimentation, further attests to the marine origin of the Romulado Formation

(Custódio *et al.*, 2017). Absence of marine sediments in the Lower Cretaceous rift basins located in between the Araripe and Potiguar basins (e.g., Rio do Peixe, Icó, Lima Campos, Iguatu and Lavras da Mangabeira basins) suggests that this portion of the continental interior might not have been inundated by marine waters in the Cretaceous Period (Arai, 2009). Paleoflow measurements of fluvial deposits below and above the Santana Formation in the Araripe and Tucano-Jatobá basins, the Marizal and Exu Formation, respectively, show a change from the southeast to west-southwest directions, indicating a redirection of regional drainage towards the Parnaíba Basin likely caused by regional uplift and tilting (Assine, 1994; Freitas *et al.*, 2017). These data suggest incipient uplift soon after the deposition of the marine units.

Aptian to Cenomanian shallow marine fossil-bearing outcrops occur at lower elevations in the onshore portions of the Atlantic rift basins (Potiguar, Pernambuco-Paraíba, Sergipe-Alagoas). Within the Potiguar Basin, shallow marine sedimentation in lagoonal, estuarine and reefal environments is recorded by the deposition of the Jandaíra Formation (92 – 91 Ma), which crops out extensively throughout the onshore portion of the basin (Pessoa Neto *et al.*, 2007; Garcia *et al.*, 2014). Additional regional paleobathymetric constraints are provided by marine stratigraphy to the west. Strontium isotope ratios, organic biomarkers and fossil assemblages indicate that the Albian Codó Formation of the Parnaíba Basin was deposited under marine conditions (Rodrigues, 1995; Antonioli *et al.*, 1999, Figure 7a).

Evidence of Cenozoic vertical motions along the modern coastal margins of this region comes from the Pirabas and Barreiras Formations (Rossetti *et al.*, 2013, Figure 7a, yellow polygons). The Pirabas Formation is a fossil-rich marine carbonate-siliciclastic deposit which crops out along Brazil’s equatorial margin. Foraminifera and pollen biostratigraphy date it as late Oligocene-early Miocene in age. Sedimentological and paleontological evidence suggests the unit was deposited in a shallow inner shelf, lagoonal, shoreface, foreshore and marginal marine environment. The Barreiras Formation overlies the Pirabas Formation, and is predominantly a siliciclastic deposit that is exposed in a ~ 100 km-wide band along the northeastern coast of Brazil. Mostly afossiliferous, chronostratigraphic constraints based on pollen and (U-Th)/He-dated overlying laterites constrain the age as early-middle Miocene, with an upper age limit of 16.45 Ma (Rossetti *et al.*, 2013). Although previously interpreted as a continental fluvial-alluvial deposit, sedimentological evidence of widespread bidirectional flow, mud drapes, reactivation surfaces, rhythmites and ichnofossils suggests a tidally influenced estuarine paleoenvironment (e.g., Rossetti and Santos Jr., 2004). The variable present-day elevation of the Pirabas and Barreiras Formations, from ~ 20 m above sea level in the equatorial and southern regions up to ~ 150 m in easternmost regions, indicates post-depositional upwarping of this paleo-surface since the mid-Miocene (Rodríguez Tribaldos *et al.*, 2017).

Within the Potiguar Basin, an angular unconformity of Aptian-Albian age (~ 110 Ma) suggests that only post-rift sediments were significantly compacted by Cretaceous to Recent sedimentation (Pessoa Neto *et al.*, 2007). The thickness of Cretaceous sediments (C_c) onshore is at most ~ 2.2 km and post-Cretaceous deposits (D) are ~ 1 km thick (Ojeda, 1983). If we assume that $\phi_o = 0.5$ and $\lambda = 3.6$ km (i.e. mean values for carbonates and clastics) the compaction correction (ΔC) is 267 m. This value is conservative as the largest thicknesses are confined to localized depressions. A similar exercise can be performed for other Atlantic rift basins. For example, the maximum value of ΔC in the Pernambuco-Paraíba Basin is 9 m (for $C_c = 397$ m, $D = 95$ m; Barbosa *et al.*, 2007), and in the Sergipe-Alagoas Basin it is 234 m (for $C_c = 1000$ m, $D = 1500$ m; Campos Neto, 2007; Ojeda, 1983). For the onshore Araripe Basin, thickness of Cretaceous stratigraphy beneath the Santana Formation is ~ 500 m, and 30–350 m of post-Santana sedimentary rock caps the Araripe plateau (Assine, 1994, 2007). Assuming that no additional sediments were deposited above the plateau (Peulvast and Bétard, 2015), ΔC ranges from 4–38 m. These maximal compaction corrections are not included in Figure 7d for simplicity.

Additional constraints on uplift and denudation in the region include the non-fossiliferous, terrestrial siliciclastic deposits of the Serra dos Martins Formation (Morais Neto *et al.*, 2009; Oliveira and Medeiros, 2012), which are found capping many high mesas in the northern Borborema Plateau. Ages of detrital apatite and zircon within these fluvial sedimentary rocks suggest sedimentary deposition cannot be older than Paleogene (Morais Neto *et al.*, 2009). These results indicate that the region was subaerial by Paleogene times. Cenozoic basalt

flows crop out atop mesas within the central and northern parts of the province: $^{40}\text{Ar}/^{39}\text{Ar}$ dating of some flows indicates that they have a minimum age of ~ 25 Ma (Menezes *et al.*, 2003; Jardim de Sá *et al.*, 2005). These observations have been interpreted as a record of Paleogene to Recent uplift. Vitrinite reflectance data, thermal maturity analysis and overcompacted sedimentary rock from the Recôncavo-Tucano-Jatobá basins in the southeastern part of the province suggest at least 1750 m of rock has been eroded since Cretaceous times (Figure 7; Magnavita *et al.*, 1994).

DISCUSSION

This study has generated a quantitative inventory of net uplift measurements from the continents and ocean islands. In the previous section, results from western North America, where the inventory is relatively dense, and the Borborema Province where recorded fossil assemblages are more sparse, were examined. In this section we explore how such uplift measurements can be used to generate useful geologic insight. Here the uplift measurements are combined with simple calibrated isostatic calculations to constrain origins of topography. To do so, we use seismological observations from the USArray experiment and a recent deployment of broadband seismometers in the Borborema province (e.g., Luz *et al.*, 2015a,b; Buehler and Shearer, 2016). This simple approach assumes that flexural rigidity of the lithosphere is sufficiently low such that uplift at wavelengths $\gtrsim 100$ km is broadly isostatic. This assumption is probably reasonable for western North America and Borborema where the relationship (admittance) between free-air gravity and topography in the frequency domain indicate elastic thicknesses, T_e , of 12 ± 2 km and 3 km, respectively (Stephenson *et al.*, 2014; Rodríguez Tribaldos *et al.*, 2017). Admittance calculated using spherical wavelets indicate similarly low ($\lesssim 20$ km) values of T_e for these regions (Audet, 2014). We acknowledge that other approaches can be used and suggest that the inventory could be helpful in assessing predictions from, for example, geodynamic models of mantle convection (e.g., Flament *et al.*, 2013).

Correlations between elevation and crustal thicknesses in western North America and the Borborema province are weak (Roberts *et al.*, 2012; Rodríguez Tribaldos *et al.*, 2017, Figure 8). Instead, the three primary candidates for generating support of topography (and uplift) are modification to the density and thickness of the lithosphere, or the convecting mantle. Following the approach of McNab *et al.* (2018) and Klöcking *et al.* (2018a), we explore the effects of lithospheric thinning, depletion and excess asthenospheric mantle temperature on the expected elevation of continents (Figure 9). Assuming isostasy prevails (i.e. flexural effects are minimal and viscous stresses related to deeper mantle flow can be neglected), the expected elevation, e , of a column of lithospheric material and associated asthenospheric mantle with respect to the depth of a standard mid-ocean ridge is given by

$$e = t_{cc} \left(\frac{\rho_L - \rho_{cc}}{\rho_a} \right) - t_w \left(\frac{\rho_a - \rho_w}{\rho_a} \right) - t_{oc} \left(\frac{\rho_a - \rho_{oc}}{\rho_a} \right) + (a - x) \left(\frac{\rho_a - \rho_L}{\rho_a} \right) + b \left(\frac{\rho_a - \rho_{ca}}{\rho_a} \right) \quad (5)$$

where t_w and ρ_w are the mean depth and density of water at a mid-ocean ridge, and t_{oc} and ρ_{oc} are the mean thickness and density of oceanic crust, respectively. t_{cc} is variable thickness of continental crust (30–40 km), ρ_{cc} is density of continental crust. a is lithospheric thickness, b is thickness of asthenospheric mantle that contributes to uplift and x is the thickness of lithospheric mantle removed. ρ_a and ρ_{ca} are densities of asthenospheric mantle beneath mid-ocean ridge and continent respectively, ρ_L is density of lithospheric mantle. The values of these parameters are calculated by assuming an adiabatic gradient and considering temperature, compressibility and putative chemical depletion (see Supplementary Material for further details). We start by assuming lithospheric thinning is instantaneous such that the geotherm has not reached steady state. Our rationale is that most of the measurements considered indicate that uplift occurred on timescales shorter than lithospheric thermal time constants (e.g., $\tau = a^2/\pi^2\kappa$; $\tau \approx 130$ Ma for $a = 200$ km, $\kappa = 10^{-6}$ m²/s). Figure 9 shows how e varies by changing t_{cc} , ρ_L , ρ_{ca} and a . Results for steady geotherms are given as Supplementary Material. These calculations are used to examine the geodynamic evolution of lithosphere and asthenosphere beneath western North America and eastern South America.

Western North America

Proposed mechanisms for uplift of the Colorado Plateau and surrounding regions include isostatic uplift from crustal thickening (e.g., *Morgan and Swanberg*, 1990; *McQuarrie and Chase*, 2000), mantle convection and shallow subduction of the Farallon slab (e.g., *Moucha et al.*, 2008b; *Liu and Gurnis*, 2010), edge-driven convection (e.g., *van Wijk et al.*, 2010), large-scale uplift by lithospheric thinning (*Roberts et al.*, 2012; *Bailey et al.*, 2012) or a combination of such processes (e.g., *Levander et al.*, 2011). We make use of the inventory of uplift constraints and simple isostatic calculations to assess the contribution of changing lithosphere thicknesses, densities, and asthenospheric thermal anomalies.

Crustal thicknesses beneath the Rocky Mountains and the Great Plains are broadly similar, ranging from 36–43 km with a mean of 40 km (Figure 8; *Buehler and Shearer*, 2016). Conversion of shear wave tomographic models into temperature indicates that the lithosphere beneath the Great Plains (e.g., Minnesota, Iowa) is ~ 200 km thick (*Priestley and McKenzie*, 2013). Solving Equation 5 using this value, a crustal thickness of 40 km and assuming that the plate rests directly upon asthenosphere that does not have excess temperature anomalies yields an elevation of 480 m. This value is consistent with the average present-day elevation of the plains (Figure 9e: red box labeled GP). However, the distribution of Cretaceous marine rock across the plains, and paleo-water depth assessments from the PBDB indicate that most of the region was at or below current sea level by as much as ~ 100 m (Figure 9e). This paleogeography is well known and used as a basis to parameterize geodynamic models of drawdown, which are often related to subduction of the Farallon Slab (e.g., *Liu and Nummedal*, 2004; *Flament et al.*, 2013). If we assume that dynamic stresses and lithospheric thickness have not changed since the Cretaceous Period, we can explore an alternative explanation where the asthenosphere directly beneath the plate was cooler than it is today. For example, a 200 km thick asthenospheric layer that has an excess temperature of -74 to -89°C yields elevations of 0 to 100 m below modern sea level. Increasing or decreasing the thickness of the layer adjusts estimated temperatures in a straightforward curvilinear way (e.g., Figure 9).

Causes for differential uplift between the Rocky Mountains and the Great Plains can be explored by considering the effects of lithospheric thinning and asthenospheric thermal anomalies (Figure 9e). We estimate the amount of lithospheric thinning beneath the Rocky Mountains by comparing its present-day thickness to thicknesses beneath the Great Plains. Figure 8a shows that conversion of shear wave tomography into estimates of lithospheric thicknesses indicates a difference of ~ 150 km. Inverse modeling of rare earth, major and trace elements from basalts across the plateau suggests that the average potential temperature of the asthenosphere beneath western North America is currently $1340 \pm 20^\circ\text{C}$. The highest values ($\sim 1365^\circ\text{C}$) are beneath the Snake River Plain, which implies excess temperatures of 0 to 45°C (*Klöcking et al.*, 2018a). These measurements predict that the asthenosphere and lithosphere support almost all of the present-day elevation of the Southern Rocky Mountains (~ 3.1 km; red box, RM; Figure 9e). Using these values and Equation 5 we suggest that Late Cretaceous-Recent uplift of the Southern Rocky Mountains can be explained by an average increase in asthenospheric temperatures of $\sim 200^\circ\text{C}$ and 150 km of lithospheric thinning (red arrows, Figure 9e). In other words, we suggest that post-Cretaceous uplift of the Rocky-Mountains-Colorado-plateaus was a result of heating of the asthenosphere that was anomalously cool during Cretaceous times to its current anomalously warm state, and thinning of the plate beneath the region. These results are consistent with interpretations of major and trace element chemistry of basaltic rock from across the region (*Klöcking et al.*, 2018a).

Borborema

Late Cretaceous shallow marine rock in the Araripe Plateau and basins along the Atlantic margin record ~ 700 m of differential uplift on a length scale of $\sim 900 - 1000$ km (Figure 7). Shear-wave-to-temperature conversions indicate that the lithosphere beneath the Araripe Plateau is ~ 150 km thick, and thins to less than 100 km at the coast (*Priestley and McKenzie*, 2013). In contrast, inverse modeling of magnetotelluric data has been used to suggest that the lithosphere beneath the Araripe Plateau is ~ 120 km thick, and surrounding lithosphere is as thick as ~ 200 km (*Garcia et al.*, 2019). H- κ stacking of receiver functions in the Borborema Province indicates that crustal thicknesses are variable ($30\text{--}41 \pm 2$ km; *Luz et al.*, 2015a). They are as low

as 30 km in the Potiguar and Sergipe-Alagoas Basins, 38 km on the eastern edge of the Araripe Basin and 40 km within the Borborema Plateau. *Luz et al.* (2015b) suggest that p-wave velocities, V_p , of the upper and lower crust beneath the Borborema plateau are 6.03–7.33 km s⁻¹. Conversion of these V_p values into density suggests crustal densities of 2.73–2.91 Mg m⁻³ (*Barton*, 1986). Inserting these values into Equation 5 indicates that present-day lithospheric and crustal thicknesses (150 and 38 km, respectively) are sufficient to explain the elevation of the Araripe Plateau without recourse to excess temperature anomalies in the asthenosphere.

A remaining question is why were significant tracts of the province marine in the Cretaceous Period? By Late Aptian times rift basins had developed along the Atlantic margin of the South American plate and within the continental interior (e.g., *Machado Júnior et al.*, 1990; *de Matos*, 1992). *Morais Neto et al.* (2009) use thermal modeling of apatite fission track data to suggest two phases of exhumation of the Borborema Plateau, during Cenomanian-Turonian and Miocene times. Their results are broadly consistent with the transition from marine to fluvial depositional environments in the Araripe, Tucano and Jatobá basins, and the presence of the marine Miocene Barreiras Formation that crops out at higher elevations along the coast (Figure 7; *Rossetti et al.*, 2013). Suggested mechanisms for Late Cretaceous to Recent uplift of the Borborema Plateau and Araripe Basin include crustal thickening by lateral flow related to Mesozoic rifting and mafic underplating driven by a deep mantle plume (*Morais Neto et al.*, 2009), emplacement of a shallow upper mantle thermal anomaly (*Ussami et al.*, 1999), localized mantle plume (*Jardim de Sá et al.*, 1999), mafic underplating (*Oliveira and Medeiros*, 2012), basin inversion caused by plate-wide compression (*Marques et al.*, 2014), and a modest, positive, asthenospheric thermal anomaly that has thinned the overlying lithosphere (*Klöcking et al.*, 2020).

We note that Late Cretaceous marine rock that outcrops near the top of the Araripe Plateau was probably deposited after rifting. Interpreted paleo-water depths of the Santana Formation are < 50 m, and the formation crops out at an elevation of 600–850 m. We tentatively suggest that one way of explaining observed vertical motions is that the asthenosphere beneath the Araripe Plateau was cooler in Cretaceous times than it is today. For example, warming of asthenosphere by 155 °C to ambient (1330 ± 15 °C) temperatures yields 995 ± 95 m of uplift (Equation 5). These results are consistent with *Klöcking et al.* (2018b, 2020) who, based on forward and inverse modeling of major, trace and rare earth element concentrations of volcanic samples, suggest a mantle potential temperature of ~ 1320 – 1340 °C. Alternatively, removal of ~ 100 km of lithospheric mantle beneath the plateau can generate observed uplift. We note if the geotherm is at steady state ~ 50 km of thinning is required (see Supplementary Material).

Remarks on limitations and further work

There are two main shortcomings in this study. The first is that we measured net uplift. Changes in uplift or subsidence rates, between marine deposition and their modern elevations, are not straightforwardly constrained using these observations. Histories of uplift can of course be refined using multiple observations of marine rock of different ages in the same or similar locations. Second, although the inventory of uplift measurements is reasonably dense in some places, there are clearly large gaps especially in continental interiors, most notably in Africa, central South America, northeastern Eurasia, and central Australia. These gaps represent a lack of marine deposition in some places. However, in others they are simply a manifestation of a partial inventory that can be improved by further work.

An obvious way to improve the inventory is inclusion of more documented marine rock. Another is addition of uplift and subsidence estimates generated using alternative approaches, for example, isotopic altimetry. We feel it is important to make a distinction between such estimates and the more direct, typically less equivocal, constraints provided by uplifted marine rock. A general challenge is designing sensible schemes to interpolate between spot measurements of uplift, subsidence and denudation. Attempts to do so have included interpolation of interpreted paleoenvironments and tectonic histories provided by geological observations (e.g., *Sahagian*, 1987; *Scotese and Golonka*, 1992; *Carena et al.*, 2019; *Markwick*, 2019). For the Cenozoic Era, a useful approach is to make use of inverse modeling of drainage patterns. This approach provides a quantitative means for filling in spatio-temporal gaps between spot measurements of uplift and denudation, and is testable using inventories of uplift such as those generated in this study (e.g., *Fernandes et al.*, 2019).

CONCLUSION

This study generated an inventory of 24,372 measurements of Cretaceous to Recent net uplift. The inventory includes measurements in all continents and many ocean islands. The measurements were generated by combining records of Cretaceous to Recent marine rock in the Paleobiology Database (PBDB) with estimates of elevation, paleobathymetry, compaction, and global sea-level change. In some places the inventory is sufficiently dense that wavelengths and amplitudes of regional uplift can be constrained (e.g., western North America; Figure 10a–c). In other places sparse measurements provide useful bounds on topographic evolution (e.g., Borborema province, Brazil; Figure 10d–f). Less than 1% of the records in the PBDB required manual modification to correct erroneously located samples. A larger effort was required to check the quality of paleo-water depth and paleoenvironment records. We have attempted to correct or remove all points that are obviously erroneous and recommend careful checking of points in regions of interest. We combine points from western North America and the Borborema province with seismological observations and simple isostatic calculations to investigate the origins of topography. In these regions post-Cretaceous net uplift has amplitudes up to ~ 1 km at wavelengths of 100–1000 km. The results indicate that spot measurements of uplifted marine rock aid understanding of sub-continental mantle dynamics and mantle-surface interactions. The inventory of uplift measurements might also provide useful constraints on paleo-environmental, -climatic and -biologic evolution.

Acknowledgments

We thank all contributors to the Paleobiology Database and A. Boyce, N. Flament, G. Hampson, A. Lipp, C. O'Malley, F. Richards, D. Sahagian, A. Whittaker and three anonymous reviewers for their helpful comments and discussion. Data Repository items are available online at www.geosociety.org/pubs/ft20XX.htm, or on request from editing@geosociety.org.

GSA Data Repository item 201Xxxx.

FIGURES

Figure 1: **Paleobiology inventory.** (a) Circles = Cretaceous to Recent marine fossils contained within the Paleobiology Database (PBDB) used to measure uplift; colors indicate mean stratigraphic age. Gray scale = hill-shaded topography (ETOPO1). Star (central western North America) = location of example shown in Figure 3. (b/c/d) Distribution of uplift constraints in western North America/Borborema Province, Brazil/NW Africa. CP = Colorado Plateau, AP = Araripe Plateau, H = Hoggar Mountains. Green polygons in panel (c) show distribution of Cretaceous marine rock including the Araripe Plateau, which is shown in the center of the panel.

Figure 2: Schematic illustrating methodology to calculate uplift. (a) Generalized stratigraphic column of Mancos Shale successions in western Colorado (see star in Figure 1a). Age constraint is based upon ammonite zones (see Biostratigraphy pane) and radiometric dating in some places (Obradovich and Cobban, 1975; Merewether and McKinney, 2015); dotted/light/dark gray bars = sand/sandy-shale/shale. Star = location of fossil assemblage shown in panel (c). (b) Schematic diagram shows information used to calculate uplift and its uncertainty. Gray = solid Earth and associated compaction (ΔC) and paleobathymetric (B) corrections; blue = sea-level correction. (c) Fossil assemblage used to constrain age and paleoenvironment of Prairie Canyon Member of the Mancos Shale (see star in panel a) from PBDB: 1–*Prognathodon* [mosasaur], 2–*Platyceramus cycloides* [bivalve], 3–*Baculites haresi* [ammonite], 4–*Squalicorax pristodontus* [shark], 5–*Baculites aquilaensis* [ammonite], 6–*Innoceramus balticus* [bivalve], 7–*Cretolamna* [shark].

Figure 3: **Bathymetric model.** Cartoon illustrates the distribution of marine paleoenvironments recorded in the PBDB. 1–basin reef, 2–basinal (carbonate), 3–basinal (siliciclastic), 4–basinal (siliceous), 5–carbonate indet., 6–coastal indet., 7–deep subtidal, 8–deep subtidal ramp, 9–deep subtidal shelf, 10–deep-water indet., 11–delta front, 12–estuary/bay, 13–foreshore, 14–interdistributary bay, 15–intraself/intraplatform reef, 16–lagoonal/restricted shallow subtidal, 17–lagoonal, 18–marginal marine indet., 19–marine indet., 20–offshore, 21–offshore indet., 22–offshore ramp, 23–offshore shelf, 24–open shallow subtidal, 25–paralic indet., 26–perireef or subreef, 27–peritidal, 28–platform/shelf-margin reef, 29–prodelta, 30–reef, buildup or bioherm, 31–sand shoal, 32–shallow subtidal indet., 33–shoreface, 34–slope, 35–slope/ramp reef, 36–submarine fan, 37–transition zone/lower shoreface. Depths are given for illustrative purposes; description of paleoenvironments is given in Table 1.

Figure 4: **Compaction correction.** Panels show calculated elevation change from decompacting rock beneath the sample (dashed line), C_c , and denudation of overlying rock, D . (a) Generalized stratigraphy of western North American example (see star in Figures 1a and 3). C_{c1} is thickness of Cretaceous sedimentary rock beneath Prairie Canyon Member of the Mancos Shale ($C_{c1} = 1.4$ km), C_{c2} is thickness of Triassic to Cretaceous rock beneath Prairie Canyon Member ($C_{c2} = 2.7$ km); thicknesses were estimated from composite stratigraphic logs (*Hintze and Kowallis, 2009*). (b) Black curve = porosity-depth function for the Piceance Basin calculated by fitting porosity-depth data from well logs (see Equation 2); initial porosity $\phi_o = 0.25$, compaction wavelength $\lambda = 3$ km (*Chapman et al., 1984*). (c) Gray scale and contours show uplift correction, ΔC , following decompaction. For this example decompacting only C_{c1} yields 0.21 km of additional uplift (red circle), and 0.31 km when C_{c2} is decompacted (blue circle).

Figure 5: **Global measurements of uplift.** (a) Circles/triangles = accurate/minimum uplift measurements generated using the PBDB. Curves labeled A–A', B–B', C–C' and D–D' are locations of swaths shown in panels (b–e). (b) Circles/triangles = uplift constraints within 100 km wide swath through North, Central and Southern America; colors = mean stratigraphic age. Major provinces are labeled. Black curve = topography along center of transect; gray polygon = extreme topography within swath. (c/d/e) Cross sections through northwest Africa/North Africa/Middle East and Eurasia.

Figure 6: Uplift of Western Interior of North America. (a) Circles = PBDB measurements colored by mean stratigraphic age; gray scale = hill-shaded topography (ETOPO1); CR = Canadian Rockies, GP = Great Plains, RM = Rocky Mountains, CP = Colorado Plateau. See Figure 1a for location. X-X', Y-Y', Z-Z' = cross sections shown in panels (e-g). (b) PBDB measurements overlaid on 1:1M geological map of North America (*Reed et al.*, 2005, see original publication for full key and unit descriptions); pЄ = PreCambrian, Pz = Paleozoic, Tr/J/IK/uK = Triassic/Jurassic/lower Cretaceous/upper Cretaceous, Cz = Cenozoic. (c) Mean paleobathymetry from PBDB inventory. (d) Mean net uplift since time of deposition from PBDB measurements. (e-g) Cross sections X-X', Y-Y', Z-Z': gray bands = topography within 100 km wide swath of central cross section (black curves); circles/triangles = mean/minimum uplift from measurements within swath; error bars = full range of paleobathymetry uncertainties.

Figure 7: **Uplift of the Borborema Plateau, NE Brazil.** (a) PBDB measurements coloured by mean stratigraphic age atop hill-shaded topography (ETOPO1); See Figure 1a for location. AR = Araripe Plateau, PT = Potiguar, PP = Pernambuco-Paraíba, SA = Sergipe-Alagoas, T = Tucano, J = Jatobá, PB = Parnaíba basins. Green polygons show location of exposed marine rock of the Santana Formation within the Araripe and Tucano-Jatobá basins (*Custódio et al., 2017*). Yellow polygons = Miocene marine Pirabas and Barreiras Formations (*Rossetti et al., 2013*). Cross sections X-X' and Y-Y' are shown in panels (e-f). (b) 1:5M geological map (*Gómez et al., 2019*). (c-d) Paleobathymetry and mean post-deposition uplift from PBDB measurements. (e-f) Cross sections X-X' and Y-Y': Topography from ETOPO1 along cross sections (black curves) and within 100 km wide swaths (gray band); coloured circles with error bars = measurements of mean uplift and paleobathymetric uncertainties within the swaths. Green bands show elevation of (Cretaceous, marine) Santana, Codó and Jandaíra Formations projected onto cross section.

Figure 8: **Cross sections through uplift and geophysical measurements.** (a) Cross section through western North America (see Figure 6: Z-Z'; color scale) showing crustal thickness from Pn -wave tomography and lithospheric thickness generated by converting a shear wave tomographic model into temperature (*Priestley and McKenzie, 2013; Buehler and Shearer, 2016*). (b) Cross section across Borborema province (see Figure 7: X-X'; color scale) showing crustal thickness from CRUST1.0 and Moho depths from H- κ stacks of P-to-S receiver functions (triangles) and lithospheric thickness (*Laske et al., 2013; Luz et al., 2015a*).

Figure 9: **Parameterization of isostatic calculations.** Top row shows predicted elevation as a function of crustal thickness, t_{cc} , and (a) % depletion, d , (density) of lithospheric mantle; (b) removed thickness of lithospheric mantle, x ; (c) asthenospheric temperature anomalies, ΔT . Middle row: Gray scale and contours show calculated elevations for a crustal thickness of 40 km and (d) depletion and thinning of the lithosphere, (e) lithospheric thinning and asthenospheric temperature anomalies, and (f) asthenospheric temperature anomalies and mantle depletion. (g)-(i) Predicted elevations for a crustal thickness of 30 km. Labeled boxes indicate estimates of support for Cretaceous western interior of North America (K), Great Plains (GP), Araripe Plateau (AR), Rocky Mountains (RM) and Potiguar Basin (PT).

Figure 10: **Schematic paleogeographies and uplift patterns from PBDB measurements.** (a) Cretaceous paleogeography of western North America. Colored circles = paleobathymetry from PBDB measurements; blue polygon = Turonian (~ 98 Ma) seaway (*Heine et al.*, 2015). (b) Modern topography (ETOPO1) overlaid with measured uplift points (colored circles). (c) Uplift (colored circles) atop long-wavelength ($\sim 800 - 2500$ km) free-air gravity (GRACE). (d–f) Paleogeography, uplift and sub-plate support of Borborema province, NW Brazil. Blue polygons in panel (d) indicate late Albian (~ 100.5 Ma) paleocoastline (*Arai*, 2009).
