Copying of entangled states and the degradation of correlations

Paweł Masiak and Peter L. Knight

We investigate the degree to which entanglement survives when a correlated pair of two–state systems are copied using either local or non–local processes. We show how the copying process degrades the entanglement, due to a residual correlation between the copied output and the copying machine (itself made of qubits).

I. INTRODUCTION

In classical information theory one can make (in principle) arbitrarily many perfect copies of any classical input. In quantum information theory, the situation is quite different. The no–cloning theorem [1] prohibits exact copying of arbitrary superposition states. Nevertheless, Bužek and Hillery and other authors [2–5] have shown that imperfect copies can be made by a Universal Quantum Cloning Machine (UQCM), the outputs of which are identical. The price which must be paid is that there is a difference between the original input and the copies, because of a residual entanglement between machine and copies. However not only similarity is lost during the cloning process. Perhaps even more important than the no–cloning feature of quantum mechanics is entanglement, that is a composite microsystem formed from some subsystems can be generated in a state $|\phi\rangle$, in which correlations between these subsystems are much stronger than any classical correlations. This quantum entanglement feature is crucial in many applications, such as some forms of quantum cryptography [6,7], relying on correlated quantum communication [8] and in quantum computation theory [9]. In all these situations success depends upon the strength of the non–local correlations. If the cloning process applied to correlated subsystems is to be anything more than a basic curiosity, and is to find a practical application in the field of quantum information theory, it should be possible to obtain not only maximally accurate copies of the original state, but also copies which preserve a degree of non–local correlation characteristic of the copied state. We will show in this paper that entanglement is rapidly destroyed by the copying process.

II. COPYING

We consider the simplest generic case of a non–local system, consisting of two qubits formed in a pure entangled state. We can choose to describe this in terms of the Bell state basis:

$|\Psi^\pm(\alpha)\rangle = \alpha|01\rangle \pm \beta|10\rangle$, 

$|\Phi^\pm(\alpha)\rangle = \alpha|00\rangle \pm \beta|11\rangle$,

where $\alpha$ determines the amount of entanglement in the state and $\beta = \sqrt{1 - \alpha^2}$. (We assume, for simplicity, that both $\alpha$ and $\beta$ are real.) There are two possibilities: the pair of qubits can be cloned locally or non–locally. Now we concentrate on the first case and restrict our considerations to the state $|\Psi^–(\alpha)\rangle$ as the results for the remaining states are entirely the same. We will explain below why they are the same for different Bell states.

A. Local cloning

A scheme which will achieve local cloning is described by the following [10]: two distant parties share an entangled two–qubit state $|\Psi^–(\alpha)\rangle$. Each of them perform some local transformations on the own qubit using distant quantum

---

On leave from Centrum Fizyki Teoretycznej Polskiej Akademii Nauk and College of Science, Al. Lotników 32/46, 02-668 Warszawa, Poland
copying machines. We assume that the two additional qubits, employed in the copying process, are initially uncorrelated. The two copiers make copies of the qubits separately. The result of the cloning process is an output which is no longer a pure state, but is described by the density matrix:

$$\hat{\rho}(\alpha) = \frac{24\alpha^2 + 1}{36} |01\rangle\langle01| + \frac{24\beta^2 + 1}{36} |10\rangle\langle10|$$

$$-\frac{4\alpha\beta}{36} (|00\rangle\langle00| + |11\rangle\langle11|) + \frac{5}{36} (|01\rangle\langle10| + |10\rangle\langle01|).$$

It is quite easy to determine whether a given pure state is local or non–local. The situation is much more complicated for the case when a system is prepared in a mixed state. There is no general method known to us which determines the degree of non–locality of mixed states. However in the case of 2 × 2 systems, there a is simple criterion which allows us to distinguish density matrices describing entangled mixed states [11,12]. The Peres-Horodecki separability criterion tells us that if the partially transposed density matrix of the composite system, defined by matrix elements generated in the following way\(\rho_{an,bm}^{\tau_2}\), does not have non–negative eigenvalues, then the state is separable. For a system formed from two two–level subsystems opposite is also true. Using the partial transposition criterion we determine for what values of the superposition parameter \(\alpha\) the final state of the local process is inseparable. The state \(\hat{\rho}(\alpha)\) is entangled when the following condition is fulfilled: \(\frac{1}{2} - \sqrt{\frac{39}{16}} \leq \alpha^2 \leq \frac{1}{2} + \sqrt{\frac{39}{16}}\).

### B. Non–local cloning

The state \(|\Psi^-(\alpha)\rangle\) can also be cloned non–locally [13,14]. In this case the entangled state of the two–qubits is treated as a state in a larger Hilbert space and cloned as a whole. The final state of each pair of the two–qubit copies at the output of the cloning machine is given by the density operator:

$$\hat{\rho} = \frac{6\alpha^2 + 1}{10} |01\rangle\langle01| + \frac{6\beta^2 + 1}{10} |10\rangle\langle10|$$

$$-\frac{3\alpha\beta}{5} (|01\rangle\langle10| + |10\rangle\langle01|) + \frac{1}{10} (|00\rangle\langle00| + |11\rangle\langle11|).$$

Now, we find the inseparability condition derived from the partial transposition criterion [11,12] is the following: \(\frac{1}{2} - \sqrt{\frac{7}{3}} \leq \alpha^2 \leq \frac{1}{2} + \sqrt{\frac{7}{3}}\).

### III. BELL INEQUALITY

The non–locality of a quantum state can manifest itself in many different ways. The best known, and one which has been tested in many experiments is the manifestation of strong nonclassical correlations of quantum states, in violation of Bell’s inequality [15,16]. The Bell–CHSH inequality [17] under consideration has the form:

$$\mathcal{B} = |E(\vec{a},\vec{b}) - E(\vec{a'},\vec{b'}) + E(\vec{a},\vec{b'}) + E(\vec{a'},\vec{b})| \leq 2,$$

where

$$E(\vec{a},\vec{b}) = \langle \hat{a} \hat{a'} \hat{b} \hat{b'} \rangle = \sum_{i,j=1}^{3} a_i b_j T_r [\hat{\rho} \hat{\sigma}^{(1)}(i) \otimes \hat{\sigma}^{(2)}(j)]$$

is the two–qubit correlation function and \(\hat{\sigma}_i\) are Pauli spin–\(\frac{1}{2}\) operators. The quantity \(\mathcal{B}\) depend strongly upon vectors \(\vec{a}, \vec{b}, \vec{a'}, \vec{b'}\). It is easy to check that for the singlet state \(|\Psi^-(\frac{1}{\sqrt{2}})\rangle\) optimal configuration, maximising \(\mathcal{B}\) is achieved by coplanar vectors \(\vec{a}, \vec{b}, \vec{a'}, \vec{b'}\), where the angles between two consecutive vectors are the same and equal to \(\pi/4\) (Fig. 1). Unfortunately this configuration is optimal only for the choice of an exact singlet initial state and actually does not fit our needs here. Instead of looking for other optimal sets of vectors, which are necessary to calculate the quantity \(\mathcal{B}\), we employ the formula for the maximal value of \(\mathcal{B}\) obtained recently by Horodecki et.al.
The $B_{\text{max}}$ can be calculated directly using the result $B_{\text{max}} = 2\sqrt{M(\hat{\rho})}$, where $M(\hat{\rho}) = \max_{i<j}(u_i + u_j)$, and $u_{i=1,2,3}$ are eigenvalues of the matrix $U(\hat{\rho}) = T(\hat{\rho})^T T(\hat{\rho})$, and $T_{i,j}(\hat{\rho}) = Tr[\hat{\rho} \hat{\sigma}_i^{(1)} \otimes \hat{\sigma}_j^{(2)}]$. Using this expression we investigate properties of copies produced from the pure entangled state $|\Psi^-(\alpha)\rangle$. These same calculations can be repeated for the other Bell states, but we have found that the results are identical to the above and independent of which state was chosen. This results from the fact that $B_{\text{max}}$ depends upon the state just by the maximum $M(\hat{\rho})$ of 

The cloning process is a fundamental quantum operation that is used in many areas of quantum information processing. It allows for the creation of multiple copies of a quantum state from a single input. In the context of entanglement, the cloning process can have significant impacts on the properties of the states involved. The density matrix, which is a fundamental tool in quantum mechanics, is used to describe the state of a quantum system. In the case of a pair of correlated qubits, one such measure is the entanglement of formation, defined as:

$$E(\hat{\rho}) = \mathcal{E}(C(\hat{\rho})),$$

where

$$C(\hat{\rho}) = \max \{0, \lambda_1 - \lambda_2 - \lambda_3 - \lambda_4\},$$

and $h(x) = -x \log_2(x) - (1-x) \log_2(1-x)$. The $\lambda_i$’s in these expressions are the square roots of eigenvalues, in decreasing order, of a non-Hermitian matrix $\hat{\rho} \hat{\sigma}$, and $\hat{\rho} = (\hat{\sigma}_x \otimes \hat{\sigma}_y) \hat{\rho}^* (\hat{\sigma}_y \otimes \hat{\sigma}_y)$. In Fig. 5 we show the entanglement of formation calculated for the pure state $|\Psi^-(\alpha)\rangle$ and the two-qubit states obtained as the result of both local and non-local copying of the state $|\Psi^+(\alpha)\rangle$. We see that non-local cloning is much more efficient than the local process, in that the values of $E$ are much larger in the former case. The entanglement of formation is in this case non-zero for states $|\Psi^-(\alpha)\rangle$, characterised by values of $\alpha$ parameter, which belong to a larger subinterval of the $[0,1]$ interval.

### A. Repetition of non-local cloning

One sees from the above that either local or non-local copying are rather inefficient processes from the point of view of preserving entanglement. Even in the case when the maximally inseparable state is the input state of the cloning process, only a small amount of entanglement survives the cloning. It is an interesting question to ask what will happen when the output state of the copier is used as an input state in the next step of a sequence of cloning processes. In particular, we are interested to discover how fast the entanglement decreases when the copying is iterated. We restrict ourselves to these considerations to the case of non-local cloning, because this scheme is much more effective as we saw above, and results obtained in this case can be treated as an upper bound for all other schemes. The final state of the copying process is a mixed state, described by the density matrix, eq.(3). This density matrix cannot be used directly as input data in computations, because the non-local copying scheme works straightforwardly only when an input state is initially in a pure, potentially entangled, state. The density matrix should be first converted to a form which allows us to perform the second cloning. It turns out that a simple diagonalization of
the density matrix is sufficient. In this new, diagonal base, the density matrix is given by the mixture of projection operators $\rho = \sum_{i=1}^{4} a_i |\phi_i \rangle \langle \phi_i|$. The weights $a_i$ in the decomposition are the eigenvalues of the density matrix $\rho$ and the vectors $|\phi_i \rangle$ are the normalised eigenvectors of $\rho$. Each vector $|\phi_i \rangle$ can be cloned separately. The mixture of the resultant density matrices taken with the weights $a_i$ is the result of the second cloning process. We repeat this procedure and investigate changes in the entanglement of formation at each stage of this procedure. In Fig. 6 we show the entanglement of formation of the clones of the states $|\Psi^-(\alpha)\rangle$ for the case of the first two stages of cloning. Results for the maximally entangled state $|\Psi^-\rangle$ are shown in Table 1.

TABLE 1. Entanglement of formation of clones of the singlet state $|\Psi^-\rangle$ as a function of the number of cloning steps.

One sees the entanglement decreases extremely rapidly, and after just three iterations the copy of any inseparable state the resultant entanglement of formation goes to zero.

V. CONCLUSIONS

We have shown that the UQCM of Bužek and Hillery [2] can generate copies of entangled pairs of qubits, but that the degree of entanglement of the resultant copies is substantially reduced. The amount of entanglement decreases very rapidly with the number of times the copier is used. States obtained as a result of either local or non–local copying do not violate already Bell’s inequality. However the entanglement of formation of such states remains still positive. It is still positive after the second step of the copying process, when output states obtained in the previous step become input states of the next step. But after the third step the entanglement of formation is equal to zero. It means that even qubits, which are copies of copies of copies of the singlet state are already in local state. They do not have any nonclassical correlations and are useless as a resource in quantum computation or quantum telecommunication. This reduction is of course due to a residual entanglement between the copies and the quantum copying machine. This is important if the copying process is used to replicate (albeit approximately) copies of a quantum register, for example, in quantum computing [3] or of a Bell–correlated quantum cryptography protocol [8].

VI. ACKNOWLEDGEMENTS

This work was supported in part by the UK Engineering and Physical Sciences Research Council, the Royal Society and the European Union. We would like to acknowledge fruitful discussions with Daniel Jonathan and Martin Plenio. We also thank Vladimir Bužek for many useful suggestions and comments on this paper.
