Abstract

Here we report the investigation of controlled PbI$_2$ secondary phase formation in CH$_3$NH$_3$PbI$_3$ (MAPI) photovoltaics through post-deposition thermal annealing, highlighting the beneficial role of PbI$_2$ on device performance. Using high-resolution transmission electron microscopy we show the location of PbI$_2$ within the active layer and propose a nucleation and growth mechanism. We discover that during the post-deposition annealing that PbI$_2$ forms mainly in the grain boundary regions of the MAPI films and that at certain temperatures the PbI$_2$ formed can be highly beneficial to device performance – reducing current-voltage hysteresis and increasing the power conversion efficiency. Our analysis shows that the MAPI grain boundaries as susceptible areas that, under thermal loading, initiate the conversion of MAPI into PbI$_2$.

Introduction

Lead halide perovskite solar cells have created significant interest since they were first proposed a little more than 5-years ago, such that now they are being referred to the next big thing in the photovoltaics industry.$^1$ The methylammonium lead halide system has been most commonly reported i.e. CH$_3$NH$_3$PbX$_3$(X=I, Br, Cl), although other mixed halide perovskites including CH$_3$NH$_3$PbI$_{3-x}$Cl$_x$, $^2$ CH$_3$NH$_3$PbI$_{3-x}$Br$_x$, $^3$ as well as formamidinium tri-iodide perovskite HC(NH)$_2$PbI$_3$ have also been reported.$^4$ Current state-of-the-art power conversion efficiencies exceed 20% in these systems,$^{5,6}$ a remarkable achievement given
that fabrication is enabled through facile solution processing routes, which have remarkable cost saving implications compared with incumbent photovoltaic technologies.\(^7\)

Post-deposition thermal annealing of the perovskite active layers has emerged as a key step in performance enhancement and film stabilization in i) the numerous solution based processing routes implemented, these include: one-step spin-coating,\(^8\) two-step sequential deposition,\(^9\) and solvent-engineering spin-coating\(^10\) and ii) the materials systems thus far developed i.e. CH\(_3\)NH\(_3\)PbI\(_{3-x}\)Cl\(_x\),\(^8\) CH\(_3\)NH\(_3\)PbI\(_3\),\(^10\) and HC(NH)\(_2\)PbI\(_3\).\(^4\) Unsurprisingly, a variety of annealing regimes have emerged with typical temperatures in the range 70 - 150 °C,\(^48\) and times from 10 minutes to > 1 hour,\(^911\) in all cases the annealing step is cited as being essential for improving power conversion efficiency (PCE) and reducing current density-voltage (J-V) hysteresis.\(^12\) Regardless of the annealing conditions cited it is apparent that this processing has a profound impact on film morphology, crystallinity and homogeneity of the perovskite layers resulting in a dramatic impact on measured device performance.\(^13\) In parallel, it has been observed that excessive or secondary annealing can decompose the active layer, irreversibly forming species including PbI\(_2\). This is exemplified by post-annealing at elevated temperature, 150 °C, for a few minutes\(^14\) or lower temperatures, ~ 100 °C, for extended periods\(^15\) where the formation of a secondary PbI\(_2\) phase is observed. To compound this issue thermally induced decomposition can be accelerated by the presence of illumination,\(^16\) moisture,\(^17\) and interfacial alkaline ligands,\(^18\) and is known to occur even at 85 °C, the upper limit of standard thermal cycling tests in inert atmosphere.\(^19\) These observations are made despite the reported decomposition temperature of CH\(_3\)NH\(_3\)PbI\(_3\) being close to 300 °C, clearly degradation occurs below 100 °C,\(^20\) \textit{perhaps} at sites such as grain boundaries,\(^21\) surfaces and interfaces. The generation of PbI\(_2\) secondary phase should therefore be considered not only in post-
deposition treatments but also during the operation under environmental and/or thermal stress.

Degradation of the perovskite absorber may therefore seem like something to be avoided, however the presence of PbI₂ can actually be beneficial to device performance. For example Chen et al have shown impressive PCE improvements, 0.66% to 12%, by thermally forming PbI₂ which is attributed to surface defect passivation.²² Alternatively, PbI₂ can also be incorporated into perovskite absorbers by adding excess PbI₂ to the precursor solution, which has been proposed as a means of reducing J-V hysteresis by blocking ionic migration.²³ As a further example, unreacted PbI₂ remaining as a secondary phase during dip-coating, is reported to suppress charge carrier recombination at the perovskite/cathode interface thus enhancing device performance.²⁴

Herein, we report the investigation of controlled PbI₂ secondary phase formation in CH₃NH₃PbI₃ (MAPI) photovoltaics through post-deposition annealing, highlighting the beneficial role of PbI₂ and through the use of high resolution transmission electron microscopy propose a nucleation and growth mechanism for PbI₂. In summary the MAPI films were prepared via a “toluene-dripping” method reported by Jeon et al¹⁰ following which brief (20 s) anneal at 100 °C was carried out on which the color of films changed from pale yellow to a characteristic dark brown. We have investigated the influence of a subsequent thermal anneal between 100 - 150 °C for 10 minutes. We discover that during the second annealing step PbI₂ forms mainly in the grain boundary regions of the MAPI films and that at certain temperatures the PbI₂ formed can be highly beneficial to device performance. Our analysis shows that the MAPI grain boundaries as susceptible areas that, under thermal loading, initiate the conversion of MAPI into PbI₂.
Results and Discussion

Typical X-ray diffraction patterns of the post-annealed MAPI films are shown in **Figure 1a**. The films annealed at 100 °C and 110 °C show the presence of polycrystalline MAPI with the (110) diffraction peak clearly visible around 14.2 ° (2θ). As temperature is increased a (001) diffraction peak of PbI₂ appears around 12.5° (2θ), which increases with intensity as temperature is raised, at 150 °C the (101) and (003) peaks of PbI₂ are also visible. Based on these data we suggest that post-deposition annealing leads to the thermal decomposition of MAPI to CH₃NH₃I (MAI) and PbI₂. The MAI is vaporized from the film due to its low sublimation temperature whilst the inorganic PbI₂ remains in the film resulting films, as confirmed by the powder diffraction patterns of PbI₂ and CH₃NH₃I (MAI) in Supplementary Figure 1. Interestingly the tetragonal structure of the MAPI is preserved on annealing, evidenced by the clear separation of the (211) and (112) diffraction peaks which may indicate that the nature of MAPI in the bulk of the films remains unchanged. We observe that PbI₂ formation appears to be a kinetically dominated process, where the content of PbI₂ secondary phase in MAPI films can be increased by either elevating the temperature or prolonging the time of post annealing.²²

**Figure 1b** shows the surface scanning electron microscopy (SEM) images of MAPI films deposited on a compact TiO₂ layer annealed between 100 – 150 °C. The pristine film (100 °C) shows a relatively flat surface with large, well-defined MAPI grains visible. As the temperature of post-annealing increases the surface homogeneity changes with an enlargement in grain size coupled with the presence of smaller granular features and pinholes. In combination with the XRD data we propose that the smaller grains and surface features (**Figure 1b vi**) may be PbI₂. Similarly, previous studies have highlighted the presence of comparable surface features.²²²⁵ However, the presence of PbI₂ cannot be
unambiguously confirmed using the SEM, either in imaging or analytical modes owing to the contribution from the surrounding MAPI contributing to signal that could be detected using e.g. energy dispersive X-ray (EDX) analysis.

To confirm the identity and location of the secondary phase we implemented scanning transmission electron microscopy (STEM) combined with high resolution transmission electron microscopy (HRTEM) to image the cross-section of glass/c-TiO₂/CH₃NH₃PbI₃/Spiro-OMeTAD structure prepared using focused ion beam (FIB) milling. **Figure 2a** and **2b** show the dark-field STEM images of the cross section, where the MAPI layer was post-annealed to 130 °C. The MAPI layer shows well-defined, tightly packed MAPI grains with grain boundaries running perpendicular to the substrate, which is similar to the appearance of MAPI films in other TEM studies ²⁶,²⁷. However, in our 130 °C post-annealed sample, in addition to the MAPI grains we also see areas of PbI₂ accompanied by voids in the film. In **Figure 2a**, grains of PbI₂ (circled in red) can be seen at the edge of a MAPI grain. The PbI₂ secondary phase appears brighter than the MAPI in the dark-field images, due to its higher average atomic number (Z). **Figure 2b** shows a PbI₂ crystal (dashed circle) penetrating the MAPI layer. It can be seen that where there are PbI₂ crystals there are also neighboring voids within the film, which appear significantly darker in STEM images due to the reduction in amount of material present in that area. We propose that the voids form in the MAPI grains as a consequence of mass transfer into the grain boundary region that initiates at/near the TiO₂ interface. The areas marked “1-4” were probed using HRTEM with the lattice fringes are shown in **Figure 2c-2f**, respectively. The presence of PbI₂ was confirmed by measuring these fringes that contained (101), (001) and (002) planes, while MAPI showed its (220) and (202) planes. The measured d-spacing in HRTEM images were compared with the d-spacings measured from XRD
patterns that are listed in Supplementary Table 1.\textsuperscript{28} Figure 2c shows a junction between TiO\textsubscript{2}, MAPI and PbI\textsubscript{2}, and Figure 2d shows an area further within the MAPI-PbI\textsubscript{2} layer. The PbI\textsubscript{2} is well aligned with the surface of TiO\textsubscript{2}, supporting the hypothesis that PbI\textsubscript{2} growth initiates at the interface of MAPI/TiO\textsubscript{2}, and subsequently propagate along the grain boundaries, or other interfaces, towards the Spiro-OMeTAD. In Figures 2e-f, the PbI\textsubscript{2} in the grain boundary shows clear (001) planes that agree with the most intensely observed XRD peaks with the (202) and (220) planes of MAPI also identified

Combining the SEM images and STEM/HRTEM images, we suggest that post-annealing leads to the formation of a PbI\textsubscript{2} secondary phase that most likely forms in the grain boundaries of the MAPI films nucleating at/near the TiO\textsubscript{2} layer and extending through the grains until it reaches the MAPI surface, as shown schematically in Figure 3. It is likely that this growth occurs for two principle reasons. Firstly, the grain boundaries provide a fast channel for the migration of lead and iodine ions. Secondly, they are open channels that allow the escape of MAI species when perovskite decomposes. We propose that the formation of PbI\textsubscript{2} starts from the surface of TiO\textsubscript{2} in the MAPI grain boundary region, and gradually propagates through the MAPI accompanied by the formation of a neighboring void. This may be associated with the nature of the chemical environment at this interface or conceivably owing to the thermal gradient that exists as the samples are post-annealed. The small grains observed by SEM in Figure 1b should indeed be PbI\textsubscript{2} crystals that have grown through the layer, and the pinholes appear when the voids neighboring the PbI\textsubscript{2} reach the film surface.

The presence of PbI\textsubscript{2} required to be advantageous to device operation can be determined through measurements of the device PCE and also considering the changes in observed
reduced $J$-$V$ hysteresis under forward and reverse bias. **Figure 4a** shows the forward and reverse scan $J$-$V$ curves of three devices in which the perovskite absorbers were annealed at 100 °C, 130 °C and 150 °C. Supplementary Figure 2 shows the schematic device structure and corresponding cross-sectional SEM images of these structures. The devices demonstrate moderate $J$-$V$ hysteresis between scans (marked by the arrows on the curves), which is suggested to be an intrinsic character of planar-structured device with TiO$_2$ as electron accepting layers. The PCE of the three devices under forward scan (FS, short circuit to open circuit) and reverse scan (RS, open circuit to short circuit) are summarized in the inset table of **Figure 4a**. Post-annealing at 130 °C resulted in an improvement in device performance compared with a post-anneal of 100 °C. Further increasing the post-annealing temperature to 150 °C resulted in a drop in device performance. Between 100 - 130 °C the increased PCE mainly arises from higher fill factor ($FF$), alongside small increase in short-circuit current ($J_{sc}$) and. The considerable improvement of $FF$ was likely due to the PbI$_2$ secondary phase in grain boundaries blocking shunt pathways.$^{24}$ The $J$-$V$ curve of 100 °C post-annealed device is characteristic of a low shunt resistance device. As grain boundaries can be highly conductive, in this state they possibly provide channels that allow direct contact between TiO$_2$ and Spiro-OMeTAD. The formation of more insulating PbI$_2$ in the grain boundaries can effectively block the shunt pathways, resulting in remarkable improvement of $FF$ shown in the $J$-$V$ curve of 130 °C post-annealed device. Further heating i.e. to 150 °C results in $J$-$V$ curves showing increased series resistance possibly due to the fact that excess PbI$_2$ increases the electronic resistivity of MAPI films. We note that PbI$_2$ formation does not sacrifice photocurrent, but rather improves $J_{sc}$. This is possibly due to enhanced absorption, shown in **Figure 4c**, and/or the passivation effect of PbI$_2$ reported previously.$^{29}$ Our $J$-$V$ curves show reduced hysteresis, **Figure 4a**, as the post-annealing temperature increased from
100 °C to 150 °C *i.e.* the reduced margin between the *J*-*V* curves in opposite scan direction. The degree of *J*-*V* hysteresis was more explicitly illustrated by the time-resolved photocurrent response in Figure 4b. The devices were held at 1.5 V *i.e.* > *V*<sub>oc</sub> in the dark and switched to short-circuit condition whilst simultaneously illuminated. The photocurrent response of all devices presented a spike followed by a decay process before reaching steady-state, where the overshoot of photocurrent contributes to the *J*-*V* hysteresis. The devices annealed at 150 °C showed the smallest photocurrent spike; in contrast the 100 °C devices show the largest. As the origin of *J*-*V* hysteresis in perovskite solar cells is considered to be a consequence of the migration of ionic species, and grain boundaries are the preferred channels for their migration, we attribute the suppressed *J*-*V* hysteresis to the PbI<sub>2</sub> in grain boundaries acting to block the motion of ionic species. The absorbance spectra the post-annealed c-TiO<sub>2</sub>/MAPI films are plotted Figure 4c. All films exhibit a clear band-edge transition at ~770 nm, the near band-edge absorbance in clearly improved with increasing annealing temperature. This is possibly due to improved film crystallinity induced by the annealing which, with the PbI<sub>2</sub> growth, may contribute to the higher *J*<sub>sc</sub> observed at elevated temperature. Additionally, changes in optical absorption have previously been used to highlight MAPI degradation<sup>2,31</sup> hence we propose that in this case the controlled formation of PbI<sub>2</sub> by moderate post-annealing does not lead to significant degradation of MAPI absorber.

We turn now to consideration of the photophysics of the MAPI films as a function of annealing temperature. Figures 5a-5c show transient absorption (TA) spectra in the visible and near infra-red range (450 nm- 800 nm) of the MAPI films with and without Spiro-OMeTAD at 1ps time after excitation at 380 nm (excitation density: 64 mJ/cm<sup>2</sup>) as a function of film annealing, whilst Figure 5d shows the transient kinetics at three probe
wavelengths for the 150 °C film. Full TA spectra at various delay times are displayed in Supplementary Figure 3, as well as data lower excitation densities. The TA spectra of MAPI films show two distinct peaks of negative optical density change (ΔOD) at ~ 480 nm (PB1, high energy photo bleaching) and ~755 nm (PB2, low energy photo bleaching/stimulated emission), respectively. The PB2 is assigned to the band edge transition of MAPI perovskite,32 while the origin of PB1 is under debate and is possibly due to a transition from a deeper valence band level (referred to hereafter as ‘VB1’) to the conduction band.33 The broad positive band in the range of 550-650 nm is due to photoinduced transient absorption.34

It is apparent from the red spectra in Figures 5a - c that as the post-annealing temperature is increased, a new bleaching peak appears at ~ 502 nm. The peak begins to emerge in the 130 °C annealed MAPI film and increases in intensity at 150 °C (highlighted by arrows). This new peak is clearly separated from the PB1 of MAPI at 480 nm. The peak position, close to the onset of PbI₂ absorption35,36 and the correlation of its appearance with our assays of annealing induced PbI₂ formation detailed above, indicate this 502 nm peak should be assigned to a PbI₂ photobleaching signal. This assignment is in agreement with a previous literature studies, although in this case the peak appearance was not directly correlated with PbI₂ formation.37 When the same samples were measured with 715 nm rather than 380 nm excitation, the 502 nm peak was no longer observed, whilst the PB1 peak of MAPI at 480 nm remained (Supplementary Figure 4), confirming that the 502 nm peak results from direct excitation of PbI₂, and is distinct from the MAPI secondary bleaching signal PB1. Figure 5d shows the dynamics of DOD decay of the 150 °C post-annealed MAPI film probed at 480 nm, 502 nm and 755 nm. The decay of PbI₂ bleaching
(502 nm) was clearly much faster than the decay of the two MAPI bleachings (480 nm and 755 nm), further supporting the different materials origins of these features.

For all samples, the TA spectra of MAPI films with Spiro-OMeTAD show lower DOD in both PB1 and PB2 than the spectra of bare MAPI films, Figure 5a-c, assigned to hole injection into Spiro-OMeTAD from the MAPI. This loss of bleach signal is most pronounced for PB1, particularly as the post-annealing temperature is increased, potentially indicating enhanced hole transfer efficiency from VB1 states. The 502 nm peak signal assigned to PbI₂ photoexcitation was particularly strongly quenched by Spiro-OMeTAD, indicating very efficient hole injection from PbI₂ to Spiro-OMeTAD. It suggests that hole injection from PbI₂ to Spiro-OMeTAD is faster than that from the main valence band of MAPI. The increased quenching of PB1 bleach by Spiro-OMeTAD with increased post-annealing temperature is suggestive that holes from the deeper VB1 may be extracted to Spiro-OMeTAD via PbI₂, in agreement with the dual valence band model proposed by Xing et al. 33.

Conclusions
In conclusion, our work shows conclusively that grain boundaries are the preferred locations for PbI₂ nucleation and growth during post deposition thermal anneal of MAPI based perovskite photovoltaic devices. By combining morphological and microstructural analysis, using X-ray diffraction and high-resolution electron microscopy, with transient optical probes we identify the benefits to device performance characteristics enabled by controllably introducing PbI₂ at the grain boundaries. We ascribe our improvements to a combination of beneficial effects, namely i) PbI₂ increasing the shunt resistance of the active layer, ii) PbI₂ reducing ionic migration and, iii) PbI₂ assisting with hole injection into Spiro-OMeTAD. We observe that temperature is an easily accessed parameter for
controlling PbI$_2$ formation and identify an optimum temperature and processing duration. Excessive thermal annealing results in the formation of too much PbI$_2$ that creates highly resistive devices. Thus by confirming the precise location of PbI$_2$ in MAPI based perovskite photovoltaics we present a logical explanation of changes in measured performance and optical characteristics and identify optimum processing conditions for producing good devices with low hysteresis.

**Experimental**

**Photovoltaic Device Fabrication**

Indium tin oxide (ITO) substrates (PsioTec, UK) were sequentially cleaned in acetone, isopropanol and deionized water for 10 minutes each using ultrasonics. The substrates were dried by nitrogen gas flow then treated by UV-ozone before film deposition. A compact TiO$_2$ blocking layer (TiO$_2$-BL) was prepared by a sol-gel method. Briefly, 350 µl titanium isopropoxide (Aldrich) was mixed with 2.5ml anhydrous ethanol then 2.5ml of anhydrous ethanol containing 35µl hydrochloride acid (HCl) was added. The mixed solution was stirred for 60 minutes and filtered before deposition. The TiO$_2$-BL film was formed by spin-coating the precursor solution on ITO substrates at 3000 rpm for 30 seconds and subsequently sintering at 500 °C for 30 minutes.
The precursor of organic-inorganic perovskite was prepared by co-dissolving 1.25 M lead iodide (PbI₂, Aldrich) and methylammonium iodide (MAI, Solaronix) in a mixed solvent of gamma-butyrolactone and dimethyl sulfoxide (Aldrich, 7:3 by volume). The solution was stirred for 2-hours and was filtered before use. The active layer was formed via the “toluene-dripping” method reported by Jeon et al.[1] The precursor solution was first spun at 500 rpm for 5 seconds and then 2000 rpm for 20 seconds. 50 ml of toluene was instantly dripped onto the film right at the end of second stage of spinning, and followed by spun at 4000 rpm for 20 seconds. The films were transferred onto a hotplate after spin-coating, and was dried at 100 °C for 20 seconds to crystalize the perovskite. The color of films changed from yellow brown to a characteristic dark brown immediately. Finally the devices were annealed at 100 - 150 °C on a hotplate for 10 minutes. Both the spin-coating and annealing process were carried out in a nitrogen-filled glovebox.

The hole transport material was prepared by dissolving 82 mg 2,2',7,7'-tetrakis[N,N-di(4-methoxyphenyl)amino]-9,9'-spirobifluorene(spiro-OMeTD, Borun Chemicals) in 1ml chlorobenzene. 15.6μl of bis(trifluoromethane)sulfonimide lithium salt (Li-TFSI, Aldrich) solution (450 mg in 1 ml of acenitrile) and 24.4 μl of 4-tert-butylpyridine (Aldrich) were added to the pristine solution as additives. The solution was stirred for 30 minutes and was filtered before use. The layer was formed by spinning the solution onto the active layer at 3000 rpm for 45 seconds. The devices were stored in dry ambient condition overnight to allow the oxidation of Spiro-OMeTAD. Finally, 60 nm-thick gold was thermally evaporated onto HTM.

**Device measurement**

Cyclic current density-voltage (J-V) characteristics were measured by applying external potential bias to the cell and recording the current with a Keithley 2400 source meter. The
cells were illuminated by an AM 1.5 xenon lamp solar simulator (Oriel Instruments). The intensity was adjusted to 1 sun by changing the working current, which was calibrated using a Si reference photodiode. All devices were stored in dark prior to measurement and were measured in a nitrogen-filled chamber. The voltage was scanned from 0V to 1.5V, back to -0.2 V and back to 0 V at a scan rate of 125 mV/s.

**Film Characterisation**

Scanning electron microscopy (SEM) images were obtained using a LEO Gemini 1525 field emission gun scanning electron microscope with a fixed operating voltage of 5 kV. X-ray diffraction (XRD) patterns were obtained using a Bruker D2 diffractometer using a Cu Kα radiation over the 2θ range 10° - 40°. Cross-sections of the devices were prepared by focused ion beam (FIB) milling using a Helios NanoLab DualBeam instrument. Sequential accelerating voltages of 30, 5 and 2 kV were used for the ion beam. The cross-section was transferred to a JEOL JEM-2100F TEM operated at 200 kV. Low-magnification images were taken under scanning TEM mode, while high-resolution images with lattice fringes were taken under conventional TEM mode. Great care was taken to minimize the exposure of the sample to the electron beam. Ultraviolet-visible (UV-vis) absorbance spectra were obtained by measuring the transmittance of perovskite film from 350 - 800 nm, with step-size of 1nm and integrating time of 0.5s. The films were deposited on glass that was coated by compact TiO₂, and annealed at 100 - 150 °C, respectively. A diluted precursor solution was used to fabricate MAPI films with three annealing temperatures (100, 130, 150 °C), in order to measure the photo bleaching signal at 450 - 550 nm. All the samples were kept in the nitrogen-filled glove box in dark for two days after deposition, and were then encapsulated with glass coverslips and Surlyn (Solaronix, Swiss) before measuring in order to prevent the degradation of samples by air. The seal was made by heating the gasket around the cell with the tip of a soldering iron. Femtosecond transient
absorption spectra were recorded by using HELIOS (Ultrafast systems). Samples were excited by a pulse train that was generated by an optical parametric amplifier, TOPAS (Light conversion). Both the spectrometer and the optical parametric amplifier were seeded with 800 nm 100 fs pulses at a repetition rate of 1 KHz, generated by a Solstice Ti:Sapphire regenerative amplifier (Newport Ltd). Before and after measuring the fs-TAS, photoluminescence spectroscopy (Horiba Fluorolog system) and electronic absorption spectra (Shimadazu UV-2600) were used to check the optical stability and the material properties.
