## Supporting Information

**ABSTRACT:** We describe a general theory for surface-catalyzed *bimolecular* reactions in responsive nanoreactors, catalytically active nanoparticles coated by a stimuli-responsive “gating” shell, whose permeability controls the activity of the process. We address two archetypal scenarios encountered in this system: the first, where two species diffusing from a bulk solution react at the catalyst’s surface, and the second, where only one of the reactants diffuses from the bulk while the other is produced at the nanoparticle surface, e.g., by light conversion. We find that in both scenarios the total catalytic rate has the same mathematical structure, once diffusion rates are properly redefined. Moreover, the diffusional fluxes of the different reactants are strongly *coupled*, providing a behavior richer than that arising in unimolecular reactions. We also show that, in stark contrast to bulk reactions, the identification of a limiting reactant is not simply determined by the relative bulk concentrations but is controlled by the nanoreactor shell permeability. Finally, we describe an application of our theory by analyzing experimental data on the reaction between hexacyanoferrate(III) and borohydride ions in responsive hydrogel-based core–shell nanoreactors.

**KEYWORDS:** *bimolecular reactions, catalysis, nanoreactors, smart polymers, permeability, diffusion-reaction theory*

## 1. INTRODUCTION

Responsive nanoreactors are an emerging and promising new molecular technology for nanocatalysis in which catalyst nanoparticles are confined in hollow nanostructures by permeable shells that can be used to shelter and control the catalytic processes. In particular, the catalysis can be made selective and responsive if the shell differentiates among molecules and if the shell permeability can be modulated by external stimuli.<sup>1–14</sup> These nanoreactors can be used for a large variety of applications, ranging from analytical tools to study chemical reactions<sup>1–12</sup> to biosensors for the diagnosis of diseases.<sup>10–14</sup> Examples of natural nanoreactors are lipid-based membranes (e.g., liposomes), cagelike proteins (e.g., ferritins), protein-based bacterial microcompartments, and viruses.<sup>11–13,15</sup> Artificial nanoreactors (based on spherical polyelectrolyte brushes, dendrimers, ligands, or even DNA) are simpler than

the natural ones and thus are easier to control for targeted applications.<sup>4–12,16,17</sup>

In recent years, nanoreactors containing metal nanoparticles coated with stimuli-responsive polymers have emerged as promising catalytic systems.<sup>4–9,18–21</sup> There are two key roles of the polymer shell. On the one hand, the shell acts as a carrier that protects nanoparticles from aggregation and hinders chemical degradation processes: e.g., oxidation.<sup>8</sup> On the other hand, the polymer ability to switch between states with different physicochemical properties upon changes in environmental parameters, e.g. temperature, pH, or concentration of certain solutes, provides a handle to actively control the nanoreactor’s catalytic properties.

**Figure 1.** Bimolecular reactions in yolk-shell nanoreactors. (a) Two reactants, A and B, diffusing from a bulk solution, generate a product, C, in the proximity of a catalyst nanoparticle. (b) Only the species A diffuses from the bulk, while the species B\* is created at the nanoparticle surface. (c) Schematic representation of a yolk-shell nanoreactor. A nanoparticle of radius  $R$  is embedded in a spherical shell of inner radius  $R_g$  and outer radius  $R_g + d$ . The shell permeability depends on the diffusivity,  $D_i(r)$ , and on the transfer free energy profiles,  $\Delta G_i(r)$ . We model both as step functions with values  $\bar{D}_i$  and  $\Delta \bar{G}_i$  inside and  $D_i^0$  and zero outside the shell, respectively.

A well-studied archetypal *active* carrier system is based on poly(*N*-isopropylacrylamide) (PNIPAM) hydrogels.<sup>4–8,18–21</sup> Here, the shell is in a swollen hydrophilic state at low temperature but sharply collapses into a hydrophobic state above the critical solution temperature.<sup>22</sup> Examples of catalytic reactions in aqueous solution studied in this system are the reductions of nitrobenzene, 4-nitrophenol, or hexacyanoferrate(III) by borohydride ions<sup>6,7,18,19</sup> and the decomposition of methyl orange under visible light.<sup>8</sup>

All the aforementioned examples deal with surface-catalyzed *bimolecular* reactions, a very common type. In the strictly unimolecular limit (as, e.g., in enzyme kinetics<sup>23</sup>), a single reactant transforms into a product once in the proximity of the nanoparticle surface. In this latter case, the total catalytic rate (reciprocal of the catalytic time) is calculated by the well-known, exact expression  $k_{\text{tot}}^{-1} = k_{\text{D}}^{-1} + k_{\text{R}}^{-1}$ , where  $k_{\text{D}}$  and  $k_{\text{R}}$  are the diffusion and the surface reaction rates, respectively.<sup>6,7,24,25</sup> Unimolecular reactions can be diffusion or surface controlled if  $k_{\text{D}} \ll k_{\text{R}}$  or  $k_{\text{D}} \gg k_{\text{R}}$ , respectively. If both rates are comparable in magnitude, the reaction is termed diffusion influenced. Analogously, a reaction is diffusion or surface controlled if  $\text{Da}_{\text{II}} \gg 1$  or  $\text{Da}_{\text{II}} \ll 1$ , where  $\text{Da}_{\text{II}} = k_{\text{tot}}/k_{\text{D}}$  is the second Damköhler number.<sup>6</sup>

As pointed out before,<sup>5–7,25</sup> pseudounimolecular surface-catalyzed reactions in responsive nanoreactors can be described by combining a thermodynamic two-state model for the polymer volume transition with the appropriate reaction-diffusion equations. In particular, the important effect of a change in the local permeability on the reactants approach to the catalyst's surface can be described by the theory of diffusion through an energy landscape,<sup>7,25,26</sup> in the spirit of Debye–Smoluchowski diffusion-controlled rate theory.<sup>27–31</sup> This theoretical framework for pseudounimolecular reactions qualitatively rationalizes the large and sharp variations in catalytic rate observed in the relevant experiments.<sup>6–8,25</sup> To this end, it was implicitly assumed that bimolecular reactions can be treated as pseudounimolecular when one of the reactants is in large excess with respect to the other. This assumption is correct for reactions in a bulk solution. However, when one considers nanoreactors, care should be taken, since in these systems it is not the bulk concentration that matters but the reactant concentration at the nanoparticle surface where the reaction can take place. The latter is strongly influenced by the shell permeability  $\mathcal{P}$ , defined as the product of reactant partitioning and diffusivity,<sup>32</sup> and can thus strongly differ from the bulk value. Due to the responsive nature of the gating shell of nanoreactors, this dependence

crucially implies that the identity of the limiting reactant can switch upon a change in the external stimulus. As we shall see later, failure to recognize this fact can lead to very large discrepancies between the exact and approximate rates.

We provide in this paper a theoretical description of *fully bimolecular*, surface-catalyzed reactions and, importantly, how they are connected and controlled to the individual reactant's permeabilities. We thus derive more comprehensive formulas of wider applicability for nanoreactors in comparison to the established unimolecular expressions. In our general scenario, *two* species A and B diffuse toward a catalyst nanoparticle, where they react together to produce another molecular species, C. Our main result is the following formula for the total catalytic rate in bimolecular reactions:

$$k_{\text{tot}} = \frac{1}{2} \left[ \frac{k_{D_A} k_{D_B}}{k_R} + k_{D_A} + k_{D_B} - \sqrt{\left( \frac{k_{D_A} k_{D_B}}{k_R} + k_{D_A} + k_{D_B} \right)^2 - 4k_{D_A} k_{D_B}} \right] \quad (1)$$

where  $k_{D_A}(\mathcal{P}_A)$  and  $k_{D_B}(\mathcal{P}_B)$  are the diffusion rates of the reactants A and B, which *explicitly* depend on the shell permeability,  $\mathcal{P}_i$ . As we will recall later, the latter is mathematically well defined within diffusion theory.<sup>32</sup> This means that, in the general case, the diffusional mass fluxes of the different reactants are strongly *coupled*, providing a behavior richer than that arising in the simple unimolecular case. Only when one of the reactants has a much larger diffusion rate than the other,  $k_{D_B} \gg k_{D_A}$ , does the total catalytic time reduce to the sum of the diffusion and the surface reaction times.  $k_{D_B} \gg k_{D_A}$  holds depending on permeability and thus on the nature and state of the nanoreactor shell. We also study the case in which only one of the species, A, diffuses from the bulk, while the other species, B\*, is created at the nanoparticle surface. We find that, with a proper redefinition of the diffusion rate, the total catalytic rate has the same form as in the case when both reactants diffuse from a bulk solution. In the case of surface-controlled reactions, our theory converges to the low reactant adsorption limit of the Langmuir–Hinshelwood mechanism.<sup>33–35</sup> With our theoretical description, we provide a firm and quantitative analysis of the conditions required for the limiting pseudounimolecular case to occur and how they are controlled by nanoreactor permeability,

clarifying when such a simplified description is indeed valid. On the basis of our theory the permeability factor can be extracted from experiments or, if available from modeling or reference experiments, used to predict the outcome of nano-reactor reaction experiments.

In the remainder of the paper, we first introduce the theory in Section 2 and then proceed to discuss key results in Section 3, where we also present its application to the analysis of experimental data.

## 2. THEORY FOR BIMOLECULAR REACTIONS

We study surface-catalyzed bimolecular reactions in so-called yolk-shell (or “hollow-shell”) nanoreactors, depicted in Figure 1. This hollow spherically symmetric configuration (see Figure 1c) is the most general we can choose, since it covers catalytic nanoparticles confined in cavities as well as core-shell nanoreactors in the limit of zero gap ( $R_g = R$ ): i.e., no hollow compartment. We consider the two following scenarios:

- **Case 1.** Two species A and B diffuse from a bulk solution kept at constant concentration  $c_{A(B)}^0$  toward the catalyst nanoparticle. A fraction (per unit of time and density of both reactants) of the reactants arriving at the surface, quantified by  $K_{\text{vol}}$ , combine to produce the third molecular species C (Figure 1a).
- **Case 2.** The species A and B combine at the nanoparticle surface as in the previous case, but only the species A diffuses from the bulk solution, whereas the species B (now denoted as B\*) is generated locally at the surface (Figure 1b).

Although it may appear artificial, the second case corresponds to the common situation where the nanoparticle surface catalyzes the production of reactive radicals of the species B\* close to it: e.g., in photochemical reactions.<sup>8</sup> These radicals rapidly decay away from the surface, so that molecules A can only react with B\* in its proximity.

The total catalytic rate,  $k_{\text{tot}}$  (number of molecules reacting per unit of time), is equal to the flux of reactants at the nanoparticle surface. In bimolecular reactions, the fraction of molecules A reacting is proportional to the number of molecules B at the same location, and vice versa. Thus,  $k_{\text{tot}}$  can be also obtained as

$$k_{\text{tot}} = K_{\text{vol}} c_A(R) c_B(R) \quad (2)$$

where  $c_{A(B)}(R)$  are the reactant concentrations at the nanoparticle surface. Equation 2 is the low reactant adsorption limit of the Langmuir-Hinshelwood mechanism.<sup>33–35</sup> To calculate  $k_{\text{tot}}$ , we solve the continuity equation for the density fields of reactants and product

$$\nabla \cdot \mathbf{J}_i = 0 \quad (3)$$

where  $\mathbf{J}_i(r)$  is the flux of the species  $i = A, B, C$  as a function of the distance from the nanoparticle. In their diffusive approach to the catalyst nanoparticle (or when they diffuse away from it), reactants (products) have to permeate the shell. The kinetics of this process is thus governed by the shell permeability,<sup>32</sup> which depends on the diffusivity profile,  $D_i(r)$ , and on the thermodynamic barrier, i.e., the transfer free energy between bulk and shell,  $\Delta G_i(r)$ . For simplicity, we take both profiles to be shell-centered step functions of width equal to the shell width  $d$  (see Figure 1c), i.e.

$$D_i(r) = \begin{cases} \bar{D}_i & R_g \leq r \leq R_g + d \\ D_i^0 & \text{elsewhere} \end{cases} \quad (4)$$

and

$$\Delta G_i(r) = \begin{cases} \Delta \bar{G}_i & R_g \leq r \leq R_g + d \\ 0 & \text{elsewhere} \end{cases} \quad (5)$$

Here,  $\bar{D}_i$  and  $D_i^0$  stand for the diffusion coefficients in the shell and solution, respectively.  $\Delta \bar{G}_i$  represents the mean interaction between the reactant and the shell (averaged over all molecular effects<sup>36</sup>) and as such strongly depends on the state (swollen/collapsed) of the nanoreactor. Equations 4 and 5 have been previously used as an approximation for spatially homogeneous gels.<sup>4–8,37</sup> Using standard thermodynamic relations,<sup>38</sup> we connect the flux of the species  $i$  to its local concentration  $c_i(r)$

$$\mathbf{J}_i = -D_i c_i \nabla \beta \mu_i \quad (6)$$

where  $\mu_i(r)$  is the chemical potential of the species  $i$ , and  $\beta = 1/k_B T$ , with  $k_B$  denoting the Boltzmann constant and  $T$  the absolute temperature of the system. The chemical potential of a molecule interacting with an external environment with a spatially dependent concentration and free energy is

$$\beta \mu_i = \ln \left( \frac{c_i}{c_i^{\text{ref}}} \right) + \beta \Delta G_i \quad (7)$$

where  $c_i^{\text{ref}}$  is a reference concentration whose value can be chosen arbitrarily. For  $\Delta G_i(r) = 0$ , eq 6 reduces to Fick's first law,  $\mathbf{J}_i = -D_i \nabla c_i$ . Using eq 7, we can obtain  $\Delta \bar{G}_i$  by measuring the partitioning of the reactants  $\mathcal{K}_i$ , defined as the ratio between their concentrations inside and outside the shell,  $c_i^{\text{in}}$  and  $c_i^0$ , respectively:

$$\mathcal{K}_i = \frac{c_i^{\text{in}}}{c_i^0} = e^{-\beta \Delta \bar{G}_i} \quad (8)$$

The partitioning in responsive polymer gels has been studied by experiment<sup>32,39,40</sup> and in terms of computer modeling<sup>36,41</sup> and theory.<sup>42</sup> With the aforementioned definitions, the shell permeability is calculated as<sup>32</sup>

$$\mathcal{P}_i = \bar{D}_i \mathcal{K}_i \quad (9)$$

We calculate the steady-state distribution of reactants and products by solving eq 3 with the appropriate boundary conditions. The full mathematical derivation, including the boundary conditions we use for both cases studied, is included in the Supporting Information, and here we just show the local reactant concentrations at the nanoparticle surface,  $r = R$ . In the case of a reactant diffusing from a bulk solution with a diffusion rate  $k_{D_{A(B)}}$  we obtain

$$c_{A(B)}(R) = \frac{c_{A(B)}^0 k_{D_{A(B)}}}{K_{\text{vol}} c_{A(B)}^0 c_{B(A)}(R) + k_{D_{A(B)}} e^{\beta \Delta G_{A(B)}(R)}} \quad (10)$$

and for a reactant B\* created at the nanoparticle surface with a creation rate  $K_{B^*}^0$  we have

$$c_{B^*}(R) = \frac{c_{B^*}^0 K_{B^*}^0}{K_{\text{vol}} c_{B^*}^0 c_A(R) + K_{B^*}^0 e^{\beta \Delta G_{B^*}(R)}} \quad (11)$$

with the permeability-dependent  $c_{B^*}^0$  defined as

$$c_{B^*}^0 = \frac{K_{B^*}^0}{4\pi} \int_R^\infty \frac{1}{\mathcal{P}_{B^*}(r)r^2} dr \quad (12)$$

The total catalytic rate is calculated using eq 2, combined with eq 10 for the first case and with eqs 10 and 11 for the second case. After some algebra (see the Supporting Information) we obtain

$$k_{\text{tot}} = \frac{1}{2} \left[ \frac{k_{D_A} k_{D_B}}{k_R} + k_{D_A} + k_{D_B} - \sqrt{\left( \frac{k_{D_A} k_{D_B}}{k_R} + k_{D_A} + k_{D_B} \right)^2 - 4k_{D_A} k_{D_B}} \right] \quad (13)$$

for both cases studied, i.e. the total catalytic rate has the same form regardless of the origin of the reactants (bulk or nanoparticle surface). In the previous expression

$$k_R = K_{\text{vol}} c_A^0 e^{-\beta \Delta G_A(R)} c_B^0 e^{-\beta \Delta G_B(R)} \quad (14)$$

stands for the surface reaction rate and

$$k_{D_i} = 4\pi c_i^0 \left[ \int_R^\infty \frac{1}{\mathcal{P}_i(r)r^2} dr \right]^{-1} \quad (15)$$

is the permeability-dependent diffusion rate of the reactant  $i$  case 1, whereas for case 2 we need to redefine  $k_{D_B} = K_{B^*}^0$ . In the absence of shell,  $\mathcal{P}_i(r) = D_i^0$ , and the diffusion rate turns into the Smoluchowski rate<sup>27</sup>  $k_{D_i}^0 = 4\pi R D_i^0 c_i^0$ . For the yolk–shell configuration depicted in Figure 1c the step profiles in eqs 4 and 5 apply and the relation between the shell permeability and the diffusion rate, eq 15, simplifies to

$$\frac{k_{D_i}}{k_{D_i}^0} = \left[ 1 + \left( \frac{D_i^0}{\mathcal{P}_i} - 1 \right) \left( \frac{R}{R_g} - \frac{R}{R_g + d} \right) \right]^{-1} \quad (16)$$

### 3. RESULTS AND DISCUSSION

Equation 13 is our main analytical result for surface-catalyzed bimolecular reactions. It shows that, in the fully bimolecular case, the diffusional fluxes of the different reactants are coupled. Thus,  $k_{\text{tot}}$  depends in a nontrivial way on the surface and the diffusion rates and nanoreactor shell permeability, in contrast to the simple unimolecular case (i.e., in general  $k_{\text{tot}}^{-1} \neq k_D^{-1} + k_R^{-1}$ ). We also find that the total catalytic rate, once the diffusion rate is properly redefined, is described by eq 13 regardless of the origin of the reactants (bulk or nanoparticle surface). For this reason, we will jointly analyze the results of both scenarios. In particular, we examine in detail the conditions required for the limiting pseudounimolecular case to occur. In addition, we use our theory to rationalize existing experimental data on the electron-transfer reaction between hexacyanoferrate(III) and borohydride ions at gold nanoparticles in responsive hydrogel-based nanoreactors.<sup>5</sup>

**3.1. Pseudounimolecular Reactions.** Bimolecular reactions are typically treated as pseudounimolecular when one of the reactants is in large excess with respect to the other.<sup>5,7,8,25,35</sup> The reasoning behind this assumption is that, according to the simple Smoluchowski rate, the reactant in larger concentration would diffuse toward the nanoparticle surface at a much larger rate than the other reactant. Therefore, when the reactant in

limiting concentration arrives to the catalyst, it will always find a reactant of the other species to combine with. However, this is not always true when nanoreactors are considered. In this case, the diffusion rate, eq 15, depends not only on the bulk reactant concentration but also on the shell permeability and thus on the molecular interactions of reactants with the shell. It is thus the combination of both quantities that determines whether a bimolecular reaction can be treated as pseudounimolecular or not. If one of the reactants has a much larger diffusion rate than the other one, e.g.  $k_{D_B} \gg k_{D_A}$ , the total reaction rate, eq 13, reduces to (see the Supporting Information)

$$k_{\text{tot}} \rightarrow k_{\text{tot}}^1 = (k_{D_A}^{-1} + k_R^{-1})^{-1} \quad (17)$$

which is the well-known expression of the total reaction rate in unimolecular reactions,  $k_{\text{tot}}^1$ . In this case, the total catalytic time is the sum of the diffusion time of the slower reactant and the surface reaction time. If both reactants diffuse from the bulk solution, according to eq 15, this condition is satisfied when  $c_B^0 \mathcal{P}_B \gg c_A^0 \mathcal{P}_A$ . This means that one of the reactants should be in much higher bulk concentration and/or subjected to a much larger shell permeability in comparison to the other. In the case where one of the reactants is created at the nanoparticle surface, we obtain  $k_{D_B} \gg k_{D_A}$  if the creation rate of  $B^*$  is much faster than the rate at which the reactants  $B^*$  are transformed into products by reactants A.

In Figure 2 we analyze how large the excess of reactant B should be for the pseudounimolecular reaction limit to be valid.

**Figure 2.** Total rate for unimolecular reactions  $k_{\text{tot}}^1$  (eq 17) divided by the total reaction rate  $k_{\text{tot}}$  for bimolecular reactions (eq 13) as a function of the relative reactant bulk concentration  $c_B^0/c_A^0$ . The different lines stand for different relative shell permeabilities to the reactants,  $\mathcal{P}_B/\mathcal{P}_A$ . We assume  $k_R = k_{D_A}$  and a typical core–shell nanoreactor geometry with  $d \gg R$ .

This value depends on the relative shell permeability,  $\mathcal{P}_B/\mathcal{P}_A$ . For simplicity, we consider that the surface rate is equal to the diffusion rate of the reactant in limiting concentration ( $k_R = k_{D_A}$ , diffusion-influenced reaction). We also consider a typical core–shell nanoreactor geometry with  $d \gg R$ . When both reactants have the same permeability (black line), the concentration of the reactant B should be roughly 10 times larger than that of A to have a unimolecular reaction. If we then decrease the shell permeability to the reactant B 10 times, its concentration thus has to become 100 times higher with respect to that of A to keep this limit (moving from darker to lighter red lines). Figure 2 also shows that the catalytic rate predicted for a

pseudounimolecular reaction for the reactant in limiting concentration may differ from the fully bimolecular rate by orders of magnitude. Thus, when one deals with nanoreactors, it is necessary to consider not only the difference between the bulk reactant concentrations but also the difference in the shell permeability to the reactants.

As a consequence, in Figure 3a we study how large the diffusion rate of the reactant B should be in comparison with that

**Figure 3.** Total rate for unimolecular reactions  $k_{\text{tot}}^1$  (eq 17) divided by the total reaction rate  $k_{\text{tot}}$  for bimolecular reactions (eq 13) as a function of the reduced surface rate values  $k_{\text{R}}/k_{\text{D}_A}$ . The different lines stand for different relative reactant diffusion rates  $k_{\text{D}_B}/k_{\text{D}_A}$ . The reddish lines (a) consider that the reactant A diffuses at a slower rate than B. The bluish lines (b) consider the opposite case. The case of equal reactant diffusion rate is shown by the black lines in (a) and (b).

of the reactant A (i.e., how large the ratio  $k_{\text{D}_B}/k_{\text{D}_A}$  should be) in order for the pseudounimolecular reaction limit to be valid. This critical value depends on the ratio between the surface rate and the diffusion rate of the slower reactant,  $k_{\text{R}}/k_{\text{D}_A}$ . If  $k_{\text{R}} \approx k_{\text{D}_A}$  (diffusion-influenced reaction), we observe that  $k_{\text{D}_B}$  must be about 1 order of magnitude larger than  $k_{\text{D}_A}$  to simplify the problem to that of a pseudounimolecular reaction within 2% accuracy. If both reactants diffuse at the same rate, the total reaction rate estimated by eq 17 is  $\sim 30\%$  larger than the real rate.

In the previous discussion we assumed that A is the limiting reactant and, consequently, we calculated the catalytic rate for unimolecular reactions given by eq 17 using its diffusion rate. In Figure 3b (the inset) we show that if the choice of the limiting reactant is wrongly made (i.e., B is the limiting reactant), the predicted unimolecular rate can be more than 1 order of magnitude larger than the real rate. The plateau reached at larger surface rates coincides with the value of the unimolecular rate considering B as the limiting reactant. We emphasize here that in stimuli-responsive nanoreactors the physicochemical properties of the shell can drastically change around a critical value of the external stimulus: e.g., from hydrophilic to hydrophobic in PNIPAM-based nanoreactors at

the critical temperature. These changes strongly affect the permeability and can thus switch the identity of the limiting reactant from one type to another. Figure 3b thus shows that, when this fact is not recognized on analyzing experiments, theoretical predictions of the rates can be off by orders of magnitude. Figure 3a also shows that, if the limiting reactant is properly identified, we can always treat a bimolecular reaction as unimolecular if the reaction is diffusion or surface controlled. This can be also inferred from eq 13. On the one hand, if the diffusion rate of the slowest reactant is much larger than the surface rate,  $k_{\text{D}_A} \gg k_{\text{R}}$ , the total catalytic rate turns into  $k_{\text{tot}} \rightarrow k_{\text{R}}$  which agrees with the surface-controlled limit for a unimolecular reaction (eq 17). On the other hand, if we take the limit of very fast surface rate,  $k_{\text{R}} \rightarrow \infty$ , we obtain (see Supporting Information)

$$k_{\text{tot}} \rightarrow \begin{cases} k_{\text{D}_A} & k_{\text{D}_A} < k_{\text{D}_B} \\ k_{\text{D}_B} & k_{\text{D}_A} > k_{\text{D}_B} \end{cases} \quad (18)$$

This means that, if the reaction at the surface of the catalytic nanoparticle is immediate, then what matters is only the diffusion time of the slower reactant. Thus, the reaction becomes pseudounimolecular and diffusion controlled. From a physical point of view, the explanation is as follows: there are so many “active” reactants at the nanoparticle surface that one of them will necessarily react whenever a reactant of the other species arrives.

**3.2. Application to Bimolecular Reactions in Responsive Core–Shell Nanoreactors.** Carregal-Romero et al. investigated the bimolecular electron transfer reaction between hexacyanoferrate(III),  $\text{Fe}(\text{CN})_6^{3-}$  (HCF), and borohydride,  $\text{BH}_4^-$ , ions in Au-PNIPAM core–shell nanoreactors.<sup>5</sup> In Figure 4a we

**Figure 4.** (a) Influence of the temperature on the measured pseudo-first-order constant in the Au-PNIPAM nanoreactors for different cross-linking densities: (■) 7% BIS; (●) 10% BIS; (▲) 15% BIS. Catalytic data are taken from ref 5. (b) Influence of the temperature on the permeability of the PNIPAM shell to HCF,  $\mathcal{P}_{\text{HCF}}^0/D_{\text{HCF}}^0$ , estimated using eq 19, for different cross-linking densities: (□) 7% BIS; (○) 10% BIS; (△) 15% BIS.

show the experimentally measured temperature-dependent catalytic rate for different *N,N'*-methylenebis(acrylamide) (BIS) cross-linking densities. We first demonstrate that the bimolecular reaction can be treated as pseudounimolecular and is diffusion controlled. Then we show how our theoretical framework can be used to analyze the experimental data and dissect the permeability into diffusion and partitioning effects, thereby providing an improved understanding of all underlying mechanistic effects in this system.

As we pointed out before, it is the combination of bulk reactant concentration and permeability that determines if a bimolecular reaction can be treated as pseudounimolecular. The ratio between the bulk borohydride and HCF concentrations is  $c_{\text{BH}_4}^0/c_{\text{HCF}}^0 = 125$  ( $c_{\text{BH}_4}^0 = 50$  mM,  $c_{\text{HCF}}^0 = 0.4$  mM). Therefore, according to Figure 2, the permeability ratio should be  $\mathcal{P}_{\text{BH}_4}/\mathcal{P}_{\text{HCF}} \gtrsim 0.1$  for the pseudounimolecular reaction limit to be valid. This is easily fulfilled, as HCF, in simple terms, is bigger and slower than the borohydride. Partitioning of HCF has been measured in microgels (with a lower cross-link density of 5%)<sup>43</sup> and indeed found to be weakly excluded, i.e. clearly  $\mathcal{K}_{\text{HCF}} < 1$ , while for the simple and small ion borohydride excluded volume effects must be expected to be smaller. In addition, the larger HCF diffuses more slowly than borohydride due to more steric “obstruction” effects.<sup>44</sup> Thus, HCF to a high certainty has a smaller shell permeability than borohydride, which means that the reaction can be treated as pseudounimolecular, with a total rate given by eq 17, HCF being the limiting reactant. In this limit, the relation between the experimentally observed rate and the calculated total rate is  $k_{\text{obs}} = k_{\text{tot}}(c_{\text{NR}}^0/c_{\text{HCF}}^0)$ ,<sup>25</sup> where  $c_{\text{NR}}^0$  stands for the nanoreactor concentration.

To discern if the reaction is diffusion or surface controlled, we estimate the observed Smoluchowski rate,  $k_{\text{D,HCF}}^0(c_{\text{NR}}^0/c_{\text{HCF}}^0) \approx 0.3\text{--}0.7$  s<sup>-1</sup> (see the Supporting Information or ref 5 for the input experimental values). According to Figure 4a,  $k_{\text{obs}} \approx 0.2$  s<sup>-1</sup> in the most “open” state of the shell: i.e., being swollen at the smallest cross-linker density. This means the reaction is diffusion controlled (consistent with common literature assumptions<sup>5,6,45</sup>), i.e.  $k_{\text{obs}} = k_{\text{D,HCF}}^0(c_{\text{NR}}^0/c_{\text{HCF}}^0)$ , with  $k_{\text{D,HCF}}^0$  given by eq 15, and the smaller observed rates for larger cross-linker densities and collapsed states must be ascribed to the decreasing shell permeability to HCF.

Now, using eq 16, we obtain the shell permeability to HCF,  $\mathcal{P}_{\text{HCF}}$ , as

$$\mathcal{P}_{\text{HCF}} = D_{\text{HCF}}^0 \left[ 1 + \left( \frac{k_{\text{D}}^0}{k_{\text{D}}^0} - 1 \right) \left( 1 - \frac{R}{R+d} \right)^{-1} \right]^{-1} \quad (19)$$

where we have already considered that the nanoreactor has a core-shell geometry,  $R_{\text{g}} = R$ .  $D_{\text{HCF}}^0 = k_{\text{B}}T/6\pi\eta(T)a$  represents the bulk diffusion coefficient of HCF, with  $\eta(T)$  being the temperature-dependent viscosity of water and  $a \approx 0.3$  nm the HCF size.<sup>5</sup> That is, the  $T$  dependence of the bulk diffusion is explicitly considered in our analysis.

We plot the temperature-dependent shell permeability to HCF calculated using eq 19 for different cross-linking densities in Figure 4b. We make use of the catalytic data ( $k_{\text{obs}}$ , shown in Figure 4a) and hydrodynamic radius data ( $r_{\text{H}} \approx R + d$ , shown in Figure S1b in the Supporting Information) measured by Carregal-Romero et al.<sup>5</sup> We see already that the measured catalytic rate,  $k_{\text{obs}}$ , does not follow the same trend with the

cross-linking density (Figure 4a) as the permeability (Figure 4b), because each system was prepared at a different nanoreactor concentration. The trend is recovered when the observed rate is normalized by  $c_{\text{NR}}^0$  (Figure S1a). Figure 4b also shows that the shell permeability to HCF switches relatively sharply at the polymer volume transition and is about 1 order of magnitude larger in the swollen than in the collapsed state of the nanoreactor, which gives rise to a larger catalytic rate (Figure 4a).

We further find that all the permeability values are below the HCF reference permeability in bulk solvent, i.e.  $\mathcal{P}_{\text{HCF}}/D_{\text{HCF}}^0 < 1$  (with  $D_{\text{HCF}}^0 \approx 0.9$  nm<sup>2</sup>/ns at 298.2 K<sup>5</sup>), which, according to eq 9, must be assigned to small partitioning and/or slow diffusion. We examine this in the following in even more detail, while we solely focus on the swollen part, as only for this case can further meaningful quantitative assumptions on diffusion be made. In the swollen state, the mobility decrease can be described by obstruction-hindered diffusion, e.g., as expressed by

$$\frac{\bar{D}_i}{D_i^0} = \left( \frac{1 - \phi}{1 + \phi} \right)^2 \quad (20)$$

$\phi$  being the PNIPAM volume fraction in the shell. This expression was developed by Mackie and Meares<sup>46</sup> to explain diffusion due to excluded-volume effects of the polymer, and it is valid for small-sized solutes in semidilute polymer solutions:<sup>44</sup> i.e., it should be applicable to the swollen state of the hydrogel.

We now separate out the diffusivity from the permeabilities to extract more quantitative numbers of the partitioning for further discussion. For the swollen state we assume the diffusivity is fully provided by eq 20, including its  $T$  dependence. For this, we calculate the PNIPAM volume fraction for different cross-linking densities as

$$\phi = \frac{V_{\text{P}}}{V} = \frac{m_{\text{P}}/\rho_{\text{P}}^0}{V} = \frac{\rho_{\text{P}}}{\rho_{\text{P}}^0} \quad (21)$$

where  $V$  stands for the whole suspension volume,  $V_{\text{P}}$  is the volume occupied by the PNIPAM in the shell,  $m_{\text{P}}$  its mass,  $\rho_{\text{P}}^0 = 1.1$  g/cm<sup>3</sup><sup>347</sup> the mass density of a PNIPAM polymer, and  $\rho_{\text{P}}$  the mean PNIPAM segment density at different cross-linking densities.<sup>48</sup> The fact that the normalized permeabilities,  $\mathcal{P}_{\text{HCF}}/D_{\text{HCF}}^0$ , are approximately constant at low temperatures indicates that the increment of the permeability with the temperature in the swollen state of the nanoreactor is mostly due to the diminution of the water viscosity with the temperature. This is not the case for the 7% BIS case, since a fully swollen nanoreactor was not achieved under the experimental conditions (see Figure S1b in the Supporting Information).

Using eq 9, we calculate the necessary partitionings to fit the permeabilities in the swollen nanoreactor state. The results are given in Table 1. Importantly, the HCF transfer free energies, predicted using eq 8, are all positive and increase with the cross-linking density. This trend is expected as the excluded volume of the shell increases with less water content and less free space. Values of the partitioning are reasonably close to those recently measured for HCF for cationic hydrogels.<sup>43</sup> Hence, our theory allows a full dissection of experimental rate and permeability effects into basic underlying mechanisms, such as bulk diffusion, hindered diffusion in the shell, and thermodynamic partitioning effects based on physical interactions. Clearly, more work is in order to understand details of molecular interactions and mobility, in particular in the collapsed state of the hydrogels.

**Table 1.** Mean PNIPAM Segment Density,  $\rho_p$ , Obtained from Ref 48,<sup>a</sup> PNIPAM Volume Fraction in the Shell,  $\phi$ , using Eq 21, Ratio between the HCF Diffusivities inside and outside the Shell,  $D_{\text{HCF}}/D_{\text{HCF}}^0$ , according to Eq 20, HCF partitioning,  $\mathcal{K}_{\text{HCF}}$ , To Fit the Permeability Data from Figure 4b in the Swollen Nanoreactor State Using Eq 9, and HCF Transfer Free Energy,  $\beta\Delta\bar{G}_{\text{HCF}}$ , Obtained by Eq 8<sup>b</sup>

BIS (%)	$\rho_p$ (g/cm <sup>3</sup> )	$\phi$	$D_{\text{HCF}}/D_{\text{HCF}}^0$	$\mathcal{K}_{\text{HCF}}$	$\beta\Delta\bar{G}_{\text{HCF}}$
7	0.14	0.13	0.6	0.4	+1.0
10	0.19	0.17	0.5	0.3	+1.2
15	0.27	0.24	0.4	0.08	+2.5

<sup>a</sup>The values at 10% and 15% BIS are calculated using a linear extrapolation. <sup>b</sup>Values are shown for different cross-linking densities in the swollen nanoreactor state.

#### 4. CONCLUSIONS

In this paper, we presented the rate theory for surface-catalyzed bimolecular reactions in responsive nanoreactors. Our theory for nanoreactors is markedly different from the treatment of standard bimolecular reactions in bulk, since the reactions here only occur at the surface of the catalyst, coupling the surface reaction rate with the permeability of the shell, which can be controlled and designed by material synthesis and stimuli in the environment. Our theory allows extracting permeabilities from experiments; alternatively, if the permeabilities are available from reference experiments or modeling, it can be employed to predict and thus rationally design nanoreactor kinetics.

We found that the total rate for bimolecular reactions depends in a nontrivial way on the reactant diffusion and surface reaction rates. More precisely, the coupling between these time scales makes it impossible to separate the process into distinct “diffusion + reaction” steps, as is the case for standard pseudounimolecular descriptions previously used to rationalize experiments (interestingly, breakdown of the standard theory can also be observed in the case of strong coupling with shell fluctuations<sup>49</sup>).

In this regard, most of the studies in the literature assume to be dealing with pseudounimolecular reactions, usually by working with one of the reactants in large excess. We show that this might not be enough: tighter conditions strongly dependent on shell permeability are required, whose breakage can lead to large error in the analysis of kinetics. This indicates that in nanoreactors one can in principle switch between pseudounimolecular and bimolecular reactions or change the identity of the limiting reactant by temperature and other stimuli. In addition, we also found that, with a proper redefinition of the diffusion rate, the total catalytic rate assumes the same form regardless of the origin of the reactants (bulk or nanoparticle surface).

As a practical demonstration, we applied our theory to available experimental data on the bimolecular electron transfer reaction between HCF and borohydride ions in Au-PNIPAM core-shell nanoreactors.<sup>5</sup> A thorough analysis of the permeability showed that the rate is governed by a complex interplay between diffusion and partitioning effects that define the shell permeability to HCF.

We finally note that our theory for bimolecular reactions is strictly valid for low adsorption of reactants only. Thus, a theory accounting for diffusion-influenced Langmuir–Hinshelwood mechanisms<sup>50</sup> in responsive nanoreactors is still needed. All of these features will highlight even richer behavior and dynamic control achievable in responsive nanoreactors.
