14 **Abstract**

15 The seed supply chain is one of most sophisticated elements of the agricultural value chain with  
16 long lead times, fragmented structure and high levels of uncertainty. Since the seed industry has  
17 received less attention in research compared with other sectors in the agriculture industry, it has  
18 enormous potential for improvement due to the lack of comprehensive mathematical  
19 optimization applications, increasing competition within the industry and decreasing spare arable  
20 land worldwide. All of the existing optimization applications in the seed supply chain have  
21 concerned land allocation at the farm level as well as regional level processing and distribution  
22 after harvesting. This research closes the gap between farm level planning and regional level  
23 distribution through optimization of seed production planning at a regional level, taking account  
24 of a number of complex constraints and practical preferences. Compared to a “business as usual”  
25 approach, the proposed application can save up to 16% of the total cost as well as 9% land usage  
26 and effectively mitigate major risks in the planning phase. The method is evaluated using  
27 Syngenta’s industrial case studies.

## 36 **Introduction**

37

38 The global population is expected to rise by one-third to 9.7 billion in 2050. This  
39 increasing population around the world will lead to demands for additional crop  
40 production as well as effectively designed supply systems for these agricultural products.  
41 The majority of these agricultural products originate from seed, thus it is even more  
42 critical to meet the demands of seed supply. Previously, the cultivated seed was  
43 traditionally saved seed from the previous season. With the advancement of technology,  
44 commercial seed products have become the more reliable and effective option compared  
45 to stored seeds. The shift from using saved seed to purchasing commercial seed products  
46 has led to the growth of the seed industry in the recent decades. There is an emerging  
47 tendency of consolidation in global seed companies as well (Howard, 2009). This trend  
48 reveals the stress from competition and the need to design more efficient systems to  
49 produce and supply seed products. Seed supply chain management generally consists of  
50 the following components:

- 51 1. Seed production planning
- 52 2. Planting based on planned portfolio
- 53 3. Harvesting of crops
- 54 4. Processing of harvested crops to packaged products
- 55 5. Distribution and storage of final products
- 56 6. Sales

57 It is an extremely long and complicated process from the planning of production  
58 allocation to the final sales in the market in the agricultural industry. Additionally, the  
59 majority of seed product is hybrid, which normally includes two parent varieties, in turn  
60 requiring more effort in the planning stage, involving production and supply of parent  
61 varieties and consideration of genetic pollution risks in production. In general, the  
62 detailed production allocation plans must be finalized at least 6 months ahead of  
63 cultivation, and the general plans should be generated for the future three years. Ideally,  
64 all these plans should be able to be updated monthly or even weekly from the initial  
65 cultivation planning to harvesting and to final sales. In other words, many highly  
66 uncertain data sets, e.g. demand and yield, are predicted at least 6 months ahead.

67 Due to the complexity involved in the seed production process, the seed production  
68 planning process can be further refined into regional level planning and field level

69 planning in each region. Based on the level of decisions, the scope of production planning  
70 can be divided into strategic, tactical and operational levels.

71 In summary, the seed supply chain is a long, complicated, fragmented and uncertain value  
72 chain. This indicates the necessity of integrating the entire process from seed growing to  
73 final sales. An effective technique to resolve and analyse all these issues is the design and  
74 optimization of effective seed supply chains. The objective of this study is to present an  
75 insight into the value that can be gained from implementing mathematical optimization in  
76 strategic seed production planning and build the initial foundation for a comprehensive  
77 framework of global supply chain optimization in the seed industry.

78

## 79 **Problem Statement**

80

81 The aim of this research is to develop a framework for the application of mathematical  
82 optimization in strategic seed production planning at a regional level. The problem  
83 statement can be summarized as follows.

84 Given:

- 85 i. Aggregated regional demand and opening stock information for different seed  
86 varieties per season
- 87 ii. Performance distribution of each growing area (yield distributions by variety and  
88 region)
- 89 iii. Regional land availability
- 90 iv. Additional business constraints
- 91 v. Additional technology and biological constraints

92 Determine:

- 93 i. Optimal allocation of land in each region for varieties considering total cost,  
94 production risk and plan robustness

95 Comhaire and Papier (2015) summarised the complexity of such tasks in Europe:

- 96 1. More than 12 months' lead time between land allocation and seed harvesting
- 97 2. Diversified geographic locations for the entire supply process with more than  
98 hundreds of seed-processing sites and thousands of supply farms
- 99 3. Regulatory variations among the various sales regions

100 In our study, the additional complexities from the particularity of the industry as well as  
101 technology restrictions have been considered, for example, the deviations in sales  
102 strategies for seed products with various maturity levels, limitations due to pollination  
103 pollution and robustness to climate variability. These requirements are interpreted as  
104 linear equality and inequality constraints available to the model to be selected based on  
105 the specific planning strategies. As the final output is directly correlated with the  
106 individual performance of the field (i.e. yield), the potential risks from variations in yields  
107 need to be considered in the quest of formulating a reliable and realistic planning model.  
108 Additionally, the uncertainty in production derived from these potential risks is  
109 incorporated into the optimization process through stochastic optimization. Therefore,  
110 this problem can be precisely defined as the development and implementation of a  
111 decision-making optimization model for large-scale strategic seed production planning  
112 under uncertainty at a regional level.

113

## 114 **Literature Review**

115

116 The seed supply chain is considered as a subset of the general Agricultural Supply Chain  
117 (ASC). Due to the comparatively low attention on the ASC until the beginning of this  
118 century, there are only a few published comprehensive reviews in the ASC field.

119 Ahumada and Villalobos (2009) undertook a comprehensive review of planning models  
120 in the agri-food supply chain; A literature review was provided by Zhang and Wilhelm  
121 (2011) for the supply chain in the specialty crops industry with a particular focus on  
122 decision support models; Lowe and Preckel (2004) presented a brief review of key  
123 agribusiness problems as well as illustrations of the needs for further research including  
124 effective decision support tools for crop production and processing. To further summarize  
125 the previous studies in ASC, the majority of the research focuses on the strategic and  
126 operational optimization of supply chain with weak connections in between. Specifically  
127 in the seed industry, its fragmented structure, long lead times and complex biological  
128 restrictions lead to additional difficulties in comprehensively investigating its supply  
129 chain. Thus there are few studies which study the practical optimization of seed supply  
130 chains. The few existing research articles emphasise strategic optimization for land  
131 allocation and harvesting schedules at a farm level as well as operational optimization for  
132 processing and distribution after harvesting.

133 With respect to research on the land allocation problem, most of the studies concentrate  
134 on a land allocation plan for limited categories of agricultural products (unlike our case  
135 with more than a hundred varieties of seeds) for individual farmers and optimal land  
136 allocation at the farm level. Heady (1954) has been widely recognised as the first  
137 demonstration of Linear Programming (LP) in agricultural land allocation problems for  
138 farmers. Huh and Lall (2013) illustrated two stochastic programming models for the  
139 optimization problems of cropping land allocation and determination of irrigation water  
140 strategies under fluctuations in weather conditions and market prices. A multi-objective  
141 deterministic allocation model was proposed by Annetts and Audsley (2002) to  
142 simultaneously evaluate profitability and sustainability through manipulating the  
143 cropping and machinery scenarios for a single farm.

144 Optimization models for seed supply after harvesting were described by Zuo et al. (1991),  
145 who presented a deterministic mathematical model for a seed corn processing and  
146 distribution system with optimal solutions and sensitivity analysis. Junqueira & Morabito  
147 (2012) built a more integrated deterministic tactical planning model after harvesting with  
148 multiple stages, plants and products as well as circulation taxes for a Brazilian seed corn  
149 company.

150 The optimization of seed production planning at a regional level can be considered as the  
151 first step to link between strategic and operational decisions in a seed supply chain. The  
152 only directly related study regarding the seed production allocation optimization problem  
153 was proposed by Comhaire and Papier (2015), describing the difficulties in seed  
154 production planning and presenting some insights into the requirements for an ideal  
155 allocation tool. There were also several attempts to incorporate dynamic programming  
156 and stochastic optimization in seed production planning, e.g. the studies of Jones *et*  
157 *al.*(2001) and Jones *et al.* (2003). However, none of these have fully implemented  
158 mathematical optimization and incorporated detailed practical constraints as well as  
159 treated uncertainty comprehensively.

160 Therefore, there is a gap in the systematic development of a tool applying modern  
161 mathematical optimization techniques to seed production planning.

162 To the best of our knowledge, there is no literature which comprehensively describes the  
163 optimization of the seed supply chain through mathematical programming with a focus on  
164 seed production planning at a regional level.

165 Therefore, this research aims to develop an innovative application using mathematical  
166 optimization in seed production planning to link the strategic and operational

167 management levels. It could act as the foundation for global optimization of the entire  
168 seed supply chain, and illustrate a successful industry – academic collaboration.

169

## 170 **Mathematical Formulation**

171

172 Due to the fragmented structure of the seed supply chain and its long lead times, some of  
173 the information used to formulate the mathematical model is uncertain, such as predicted  
174 yield and predicted demand with more than one year’s lead time. The stochastic nature of  
175 various input information (e.g. demand forecast and yield) as well as the annual cycle in  
176 the production process make it practically meaningless to consider a dynamic process  
177 with more than one year’s lead time, i.e. this problem is considered as a static planning  
178 problem. From the perspective of systematic development, it is more effective to  
179 assemble the fragments into a framework assuming all the uncertain information is  
180 deterministic, i.e. assume a deterministic optimization model. Afterwards, the uncertainty  
181 can be incorporated into the deterministic framework to increase the reliability of the  
182 model. In this study, a simplified two – stage stochastic optimization model is  
183 subsequently developed to demonstrate some of the insights associated with uncertainty.

## 184 **Notation Table**

185

186 For the sake of readability, the term hybrid indicates the final seed product to be sold to  
187 the market, male variety represents the parent male seed used to plant the hybrid.

188

### 189 *Indices*

c	Growing country
i	Growing region
j	Seed product (Hybrid)
k	Sales group
m	Male varieties
s	Scenario

191 *Continuous non-negative parameter*

$D_j$	Demand of hybrid $j$ (bag)
$MnA_{i,j}$	Minimum amount of land to be allocated to hybrid $j$ in growing region $i$ (ha)
$MnGC_j$	Minimum number of growing countries of hybrid $j$
$MnGR_j$	Minimum number of growing regions of hybrid $j$
$MnL_i$	Minimum amount of land to be allocated in growing region $i$ (ha)
$MxI_i$	Maximum number of isolations in growing region $i$
$MxL_i$	Maximum amount of land to be allocated in growing region $i$ (ha)
$MxP_{i,j}$	Maximum production volume of hybrid crop $j$ in growing region $j$ (bag)
$MxPre_j$	Max weighted preference of hybrid $j$
$MxTVar_k$	Maximum average variability of sales group $k$
$MxVar_j$	Maximum variability of hybrid $j$
$OP$	Penalty cost for overproduction ((\$/bag)
$OS_j$	Opening stock of hybrid $j$ (bag)
$Pre_{i,j}$	Preference index of hybrid $j$ produced in growing region $i$
$SP$	Penalty cost for shortage (\$/bag)
$SPO_k$	Penalty cost for overproduction for sales group $k$ in stochastic model (\$/bag)
$SPro_s$	Probability for the occurrence of scenario $s$
$SPS_k$	Penalty cost for shortage for sales group $k$ in stochastic model (\$/bag)
$SY_{s,i,j}$	Yield of hybrid $j$ grown in growing region $i$ in scenario $s$ (bag/ha)

$UG_{i,j}$	Growing cost of hybrid $j$ in growing region $i$ per hectare (\$/ha)
$UP_{i,j}$	Unit processing cost of hybrid $j$ in growing region $i$ (\$/bag)
$UT_{i,j}$	Unit transport cost of hybrid $j$ in growing region $i$ (\$/bag)
$V_{i,j}$	Variance of hybrid $j$ harvested in growing region $i$
$Y_{i,j}$	Yield of hybrid $j$ growing region $i$ (bag/ha)
$\bar{Y}_j$	Average yield of hybrid $j$ among all the growing regions (bag/ha)

192 *Binary parameter*

$CAM_{c,i}$	Binary parameter indicating the membership between growing region $i$ and growing country $c$
$HPM_{j,m}$	Binary parameter indicating the membership between hybrid $j$ and corresponding male variety $m$
$SG_{k,j}$	Binary parameter presenting the membership between sales group $k$ and hybrid $j$

193

194 *Continuous non – negative variables*

195

$CS_j$	Deterministic closing stock of hybrid $j$ (bag)
$EOC$	Expected value of overproduction penalty cost in stochastic model (\$)
$EPC$	Expected value of processing cost in stochastic model (\$)
$ESC$	Expected value of shortage penalty cost in stochastic model (\$)
$ETC$	Expected value of transportation cost in stochastic model (\$)

$GC$	Total growing cost (\$)
$LA_{i,j}$	Amount of land allocated to hybrid $j$ in growing region $i$ (ha)
$OC$	Total deterministic overproduction penalty cost (\$)
$PC$	Total deterministic processing cost (\$)
$S_j$	Deterministic shortage of hybrid $j$ (unit)
$SC$	Total deterministic shortage penalty cost (\$)
$SO_{s,j}$	Total stochastic overproduction of hybrid $j$ in scenario $s$ (bag)
$SS_{s,j}$	Stochastic shortage of hybrid $j$ in scenario $s$ (bag)
$STC$	Total cost in stochastic model (\$)
$STP_{s,j}$	Total stochastic production of hybrid $j$ in scenario $s$ (bag)
$TC$	Total deterministic cost (\$)
$TP_j$	Total deterministic production of hybrid $j$ (bag)
$TPre_j$	Total preference of hybrid $j$
$TraC$	Total deterministic transportation cost (\$)
$TVar_k$	Total average variability of sales group $k$
$Var_j$	Variability of hybrid $j$

196

197 **Binary variables**

$x_{i,j}$	1 if hybrid $j$ is planned to be grown in growing region $i$ ; 0 otherwise
$xO_{s,j}$	1 if hybrid $j$ is overproduced in scenario $s$ ; 0 otherwise
$xP_{i,m}$	1 if male variety $m$ is grown in growing region $i$ ; 0 otherwise

$xu_{s,j}$  1 if hybrid  $j$  is under-produced in scenario  $s$ ; 0 otherwise

$y_{c,j}$  1 if hybrid  $j$  is planned to be grown in growing country  $c$ ; 0 otherwise

198

## 199 **Deterministic Model**

200

201 In this section, the framework of our mathematical model assuming deterministic  
202 information is introduced including the objective function as well as both the equality and  
203 inequality constraints. This serves to describe the deterministic planning model  
204 effectively. Later we shall introduce the stochastic elements.

### 205 *Objective Function*

206

207 The objective of this MILP is to minimize the total cost subject to a series of hard and  
208 soft constraints; the basic components for the seed production process are growing,  
209 processing and distribution, thus the total cost can be further classified into growing cost,  
210 processing cost and transportation cost. In this regional level model, the land allocated to  
211 each product  $j$  in each growing region  $i$  is regarded as a continuous decision variable  
212 and is the most important decision variable. The growing cost is estimated as the product  
213 of land usage and unit growing land cost, while both the processing cost and  
214 transportation cost are represented by production volume multiplied by the corresponding  
215 unit cost. An extra penalty cost for shortages (i.e. demand shortfalls) is generated to avoid  
216 infeasible solutions.

$$GC = \sum_i \sum_j LA_{i,j} \times UG_{i,j} \quad (1)$$

$$PC = \sum_i \sum_j LA_{i,j} \times Y_{i,j} \times UP_{i,j} \quad (2)$$

$$TraC = \sum_i \sum_j LA_{i,j} \times Y_{i,j} \times UT_{i,j} \quad (3)$$

$$SC = \sum_j SP \times S_j \quad (4)$$

$$OC = \sum_j OP \times CS_j \quad (5)$$

$$TC = GC + PC + TraC + SC + OC \quad (6)$$

217

218 **Basic Constraints**

219

220 The primary constraints for this problem can be categorized into six types; they are all  
221 essential to ensure the practical applicability of the seed production planning model.

222

223 **Demand Balance**

224

225 The demand constraint can be described as the mass balance accounting for total  
226 production, opening stock of product  $j$  and demand, with the shortage variable and  
227 closing stock variable being added to avoid any infeasibility due to unachievable demand  
228 or over-constrained production volume respectively.

$$TP_j = \sum_i Y_{i,j} \times LA_{i,j} \quad (7)$$

$$CS_j + D_j = OS_j + TP_j + S_j \quad (8)$$

229

230 **Regional level land availability**

231

232 The total available land in each growing region is considered as the maximum accessible  
233 and arable land belonging to the company and its potential third party contractors to be  
234 allocated in each region, meanwhile the minimum land allocation in each growing area is  
235 intended to represent the minimum contracted land to be used in each growing region,  
236 and this is an important consideration to ensure continuity of business in the region.

$$MnL_i \leq \sum_j LA_{i,j} \leq MxL_i \quad (9)$$

237

238 **Land allocation**

239

240 It is not profitable to allocate land in a particular region to a product below a minimum  
241 practical level. Thus, an additional binary decision variable ( $x_{i,j}$ ) is implemented to  
242 indicate this discrete limitation.

$$x_{i,j} \times MnA_{i,j} \leq LA_{i,j} \leq x_{i,j} \times MxL_i \quad (10)$$

243

244 **Biological constraint**

245

246 Nowadays the majority of the seeds are grown as hybrids, i.e. the offspring of two parent  
247 varieties. Theoretically one hybrid is the offspring of one male variety and one female  
248 variety, and the nearby existence of any other male variety will affect the quality of  
249 pollination, i.e. pollution in pollination. Practically, the pollution in pollination can be  
250 effectively avoided by isolating hybrids with different male varieties. Based on the  
251 limitation from the previous constraint (Land allocation), the number of isolation blocks  
252 available to each grower is limited, thus the maximum number of isolation blocks within  
253 each growing region should be limited according to the limitations associated with  
254 growers. In order to properly interpret this constraint, an extra binary decision variable  
255 ( $xp_{i,m}$ ) is used to indicate the presence of particular male varieties in each region. An  
256 extra binary parameter ( $HPM_{j,m}$ ) is used to reveal the correlation between two types of  
257 decision variables ( $x_{i,j}$  and  $xp_{i,m}$ ) to ensure a correct mapping between varieties ( $j$ ) and  
258 males ( $m$ ).

$$\sum_m xp_{i,m} \leq MxI_i \quad (11)$$

$$HPM_{j,m} \times x_{i,j} \leq xp_{i,m} \leq \sum_j HPM_{j,m} \times x_{i,j} \quad (12)$$

259

260 Constraint (12) defines this variable and constraint (11) ensures that the maximum  
261 number of isolation blocks is not violated.

262 **Distribution limitations**

263

264 Due to the differences in the policy of each country, it is impossible to transport certain  
265 biological products between certain countries. The maximum production volume for each  
266 product in each growing region is thus applied to simplify this distribution limit at a  
267 regional level.

$$Y_{i,j} \times LA_{i,j} \leq MxP_{i,j} \quad (13)$$

268

269

270

### 271 **Commercial importance of the products**

272

273 From the perspective of the business, the commercial importance of each product depends  
274 on its maturity as a product and potential within the market, i.e. the sales targets for the  
275 products with various relative significance levels are different. The most important  
276 products with highest potential are the newly developed seeds with lowest product  
277 maturity as well as highest future sales potential. The mature seeds are less important and  
278 the old products with high product maturity as well as lower potential in the market are  
279 grown with the lowest priority. The level of importance represents the desired “stability”  
280 of production; more important products require more stable production, i.e. lower risk of  
281 variation in production. Even though it is difficult to directly interpret this constraint in a  
282 deterministic model, it can be indirectly estimated through two types of extra constraints:  
283 minimum number of growing regions/countries and tuneable risk constraints.

284 In practical field production, a very unfavourable event could lead to the complete loss of  
285 all the crops within entire field. It has been known to happen, but it is impossible to  
286 precisely quantify or forecast all the unpredictable factors/events, e.g. extreme weather  
287 conditions and sudden changes of temperature. The first factor can be considered as the  
288 “foundation” to manually enforce the minimal number of growing regions and growing  
289 countries, so that the overall production can be made more robust by diversifying the  
290 growing regions and countries, i.e. limiting the maximum amount of production of one  
291 hybrid in one particular location. In case of an extreme event occurring, the  
292 diversification will reduce the risk of total production loss. The number of growing  
293 regions for a hybrid can be evaluated by the summation of binary variable  $x_{i,j}$  for all  
294 growing regions. The new binary decision variable ( $y_{c,j}$ ) is added to indicate the  
295 existence of seed production in each country. Similar to the biological constraint, an extra  
296 binary parameter is implemented to reveal the correlation between  $x_{i,j}$  and  $y_{c,j}$ .

$$MnGR_j \leq \sum_i x_{i,j} \quad (14)$$

$$MnGC_j \leq \sum_c y_{c,j} \quad (15)$$

$$x_{i,j} \times CAM_{c,i} \leq y_{c,j} \leq \sum_i x_{i,j} \times CAM_{c,i} \quad (16)$$

297

298

299

### 300 **Risk Constraints – Yield Uncertainty**

301

302 Even though the uncertainty in production cannot be comprehensively captured in a  
 303 deterministic model, the risk involved in the optimization model can be constrained based  
 304 on the maximum level of uncertainty in production. Unlike the basic constraints described  
 305 previously, the strength of the risk constraints is determined by the risk appetite in a  
 306 specific problem setting. Two approaches are introduced by the company to limit the  
 307 level of stability.

308 1. “Preference” of Production

309 2. “Variability” of Production

310 The preference of production is decided using a user defined preference index determined  
 311 by the industry specialists based on experience with different varieties and different  
 312 growing regions to manipulate the risk involved in production. The preference index is  
 313 defined for each valid variety and growing region pair. A lower preference index  
 314 represents a lower historical risk associated with that hybrid – region allocation as well as  
 315 higher stability in harvesting. The preference index is subjective and implies a qualitative  
 316 but accessible view of risk. Meanwhile, it reveals less dependence on the accuracy of the  
 317 risk information due to its high level of abstraction in the risk of production. In other  
 318 words, the constraint for the preference of production can only be qualitatively considered  
 319 as an indicator of risk.

320 The total preference index of product  $j$  is normalized by average land allocation of  
 321 hybrid  $j$ .

$$TPre_j = \frac{\bar{Y}_j \times \sum_i Pre_{i,j} \times LA_{i,j}}{D_j} \quad (17)$$

322

323 Referring to the commercial importance of the products described previously, the  
 324 industrial specialists have reference values for the importance of each product, and based  
 325 on these references, they will estimate the levels of preference of each product through  
 326 their experience. A simplified approach to achieve such a limitation is to define the upper  
 327 bound of the total preference of each product, noting that this is a risk measure and hence  
 328 constrained from above ( the effect of this measure can be explained through sensitivity  
 329 analysis):

$$TPre_j \leq MxPre_j \quad (18)$$

330

331 As introduced previously, preference can only be qualitatively considered as an indicator  
 332 of risk. In case where variances of the yields (assuming the yield is normally distributed)  
 333 are available with limited accuracy, the variability constraints presented in (19) – (22) can  
 334 be applied instead. The variability is defined as the ratio of deviation caused by variance  
 335 in harvesting normalized by demand. The variability of each product is constrained by a  
 336 manually determined upper bound.

$$Var_j = \frac{\sum_i Y_{i,j} \times LA_{i,j} \times V_{i,j}}{D_j} \quad (19)$$

$$Var_j \leq MxVar_j \quad (20)$$

337

338 The advantage of the variability constraint is its quantitative representation of the risk in  
 339 production, thus it can be incorporated together with a minimum number of growing  
 340 regions/countries to capture the importance of different seeds. In terms of sales targets,  
 341 vital products require a stable planting strategy and cost is less critical while the declining  
 342 products are driven by cost regardless of stability or potential shortage. From the  
 343 perspective of harvesting, the newly developed seeds with less mature technology are  
 344 inherently unstable. It is not practical only to manage the variability through constraint  
 345 (19) and constraint (20) for each product. Additionally, the average variability within  
 346 each sales group is constrained to simultaneously achieve different objectives.

$$TVar_k = \frac{\sum_j SG_{k,j} \times Var_j}{\sum_j SG_{k,j}} \quad (21)$$

$$TVar_k \leq MxTVar_k \quad (22)$$

347

348 A similar approach can be applied for the preference constraints, however it is harder to  
349 “tune” these as they have a higher level of subjectivity and approximation compared with  
350 variability, which is a statistical quantity.

351 To summarize the risk constraints, either preference or variability should be selected to  
352 control and quantify the stability of production in the case of insufficient predicted future  
353 information. The preference constraint is more qualitative and has less dependence on the  
354 risk information but less controllability, while the variability is more flexible and  
355 practical to manipulate but it requires quantitative uncertainty information (e.g. variance).

356 The combination of minimum numbers of growing regions/countries, which qualitatively  
357 reduce the effect from unexpected extreme events, and tuneable risk constraints, which  
358 constrain the level of stability in production, is introduced to reduce the risk in production  
359 for the deterministic model.

360 In the next section, we extend the deterministic analysis to include stochastic elements  
361 with a focus on yield uncertainty.

## 362 **Stochastic Model**

363

364 The risk associated with production in this problem can be specifically defined as the  
365 uncertainty in the yield which is only observed during harvesting. The effect of  
366 uncertainty can only be partially reduced in the previous deterministic model. In order to  
367 further optimize the seed production planning process together with risk, both stochastic  
368 information and the modified model incorporating uncertainty should be implemented  
369 instead. In this study, the insights and benefits of applying stochastic optimization are  
370 demonstrated by assuming a description of uncertainty (e.g. predicted yield distribution)  
371 is available with practical reliability. Hence the practicality of the model can be further  
372 improved and the impacts from uncertainty can be further eliminated through a simplified  
373 two – stage stochastic optimization.

374 For stochastic optimization of seed production planning, the scenario – based approach is  
375 applied to construct the deterministic equivalent for the stochastic linear programme.

376 Normally, the algorithm used in a deterministic model is also applicable for this type of  
377 stochastic model.

378 In this section, the reformulations required to convert the deterministic model to a  
 379 stochastic model are described first followed by the specifications of objective function  
 380 and constraints for the reformulated model.

381 *Reformulation of the model*

382

383 The deterministic model introduced previously can be regarded as the framework for  
 384 modelling seed production planning. The remaining issue to be considered is the effect  
 385 from uncertain information. In this study, a simplified two – stage stochastic optimization  
 386 method is applied to balance the influences from uncertainty.

387 Since this model is built to demonstrate the value of a stochastic model, only the yields of  
 388 crops are considered as uncertain parameters and all the practical decisions are assumed  
 389 to be made in the first stage, i.e. land allocation of hybrid by growing region. The actions  
 390 in the second stage are harvesting, processing and transportation, as a simplified  
 391 stochastic model in this study, all these practical decision variables from the second stage  
 392 are neglected due to limited availability of practical data. Only the decision variables  
 393 regarding closing stock and shortage in production of hybrid by scenario are considered  
 394 from the second stage to avoid infeasibility due to shortage or overproduction. The  
 395 dependent variable related to harvesting is the total volume of production and volume of  
 396 underproduction (shortage). An extra variable for overproduction is also generated due to  
 397 the variations in production volumes in the second stage. The demand balance is  
 398 reformulated with the additional dimension of scenarios.

$$STP_{s,j} = \sum_i SY_{s,i,j} \times LA_{i,j} \quad (23)$$

$$SO_{s,j} + D_j = OS_j + STP_{s,j} + SS_{s,j} \quad (24)$$

399

400 From a practical point of view, both shortage which leads to unfulfilled demand and  
 401 reduced customer satisfaction and overproduction which leads to additional inventory  
 402 cost) are not desired. Shortage and overproduction cannot occur simultaneously for a  
 403 particular hybrid, thus two additional binary variables are generated to avoid the possible  
 404 coexistence of overproduction and underproduction.

$$x_{0s,j} \leq SO_{s,j} \leq x_{0s,j} \times D_j \quad (25)$$

$$xu_{s,j} \leq SS_{s,j} \leq xo_{s,j} \times D_j \quad (26)$$

$$xo_{s,j} + xu_{s,j} \leq 1 \quad (27)$$

405

406 Considering perishability and sensitivity of seed products, overproduction may even be  
 407 more critical than shortage to ensure operational efficiency of the company. A penalty  
 408 cost for overproduction is added to quantify the effect of overproduction and minimize  
 409 the impact from it. The expected values of overproduction and shortage cost are  
 410 calculated in the objective function. The penalty cost for the overproduction and shortage  
 411 can be formulated with a penalty cost dependent on each sales group.

$$EOC = \sum_k \sum_s \sum_j SG_{k,j} \times SPro_s \times SPO_k \times SO_{s,j} \quad (28)$$

$$ESC = \sum_k \sum_s \sum_j SG_{k,j} \times SPro_s \times SPS_k \times SS_{s,j} \quad (29)$$

412

413 In terms of actions related to processing and distribution, the deterministic processing and  
 414 transportation cost are reformulated to the corresponding mathematical expectation of all  
 415 possible scenarios.

$$EPC = \sum_s \sum_i \sum_j SPro_s \times LA_{i,j} \times SY_{s,i,j} \times UP_{i,j} \quad (30)$$

$$ETC = \sum_s \sum_i \sum_j SPro_s \times LA_{i,j} \times SY_{s,i,j} \times UT_{i,j} \quad (31)$$

416

### 417 *Objective Function*

418

419 The deterministic equivalent objective function is the summation of the deterministic  
 420 growing cost as well as expected values of processing, transportation, overproduction  
 421 penalty and shortage penalty cost.

$$STC = GC + EPC + ETC + EOC + ESC \quad (32)$$

422

423 Due to the incorporation of the yield probability distribution, the objective function can  
424 be specified based on the relative importance of the seed product. Both penalty costs for  
425 overproduction and shortage can be manipulated independently according to the specific  
426 targets for different varieties.

427

#### 428 *Constraints*

429

430 Other than the reformulated demand balance introduced previously, the land availability,  
431 existence of land allocation, biological constraint and distribution limit described in the  
432 basic constraints of the deterministic model can be applied without any modification  
433 since there are no scenario – dependent second stage variables involved. Regarding the  
434 constraint concerning the relative importance of each product, it is interpreted directly  
435 through sales group dependent tuneable penalty costs in the objective function. However,  
436 the minimal number of growing regions can be incorporated with relaxed bounds as  
437 insurance to avoid any significant impact from inaccurate uncertainty descriptions. For  
438 example, the minimum number of growing regions is set to 4 for one certain seed product  
439 in the deterministic model, and that value can be reduced, e.g. 3 or 2, in the stochastic  
440 model to reduce the effects from inaccurate information while preventing unnecessary  
441 subjective restrictions from this type of constraint. The additional risk constraints  
442 implemented in the deterministic model should not be utilized in the stochastic model,  
443 otherwise the subjective restrictions from risk constraints will affect the optimality and  
444 feasibility of stochastic optimization.

#### 445 **Demand uncertainty**

446

447 Compared with risk in production, demand will be more challenging to accurately predict  
448 as it will be dependent on various stochastic process, futures prices, exchange rate and  
449 farmers' choices. Combined with internal uncertainty, such as inventory level for next  
450 year (at the time of production planning for next season, sales for the current season are  
451 not finished yet), accurate demand forecasting will not be a simple problem being solved  
452 in the short term. From the perspective of production planning optimization, theoretically,  
453 it will be an option to extend the model to incorporate demand uncertainty through  
454 stochastic optimization or robust optimization.

455 However, practically it is not a currently feasible option due to the unavailability of  
456 accurate data for demand forecasts.

## 457 **Case Study and Results**

458

459 Real world data from Syngenta have been incorporated into the models introduced  
460 previously to undertake case studies and evaluate the benefits of optimization, and form  
461 the basis of a decision support tool. The industrial application of deterministic models is  
462 described initially followed by the application of the reformulated stochastic model. The  
463 purpose of this study is to present insights into the value of implementing strategic  
464 optimization in seed production planning. Before the implementation of mathematical  
465 optimization in the strategic seed production planning process, planning experts from the  
466 company used an iterative approach to manually allocate the required production amounts  
467 into available production regions within a spreadsheet tool.

468 All the mathematical models described in this section are built in GAMS 24.5.6 and  
469 solved by the commercial solver CPLEX 12.6.1.

470

471

### 472 **Initial Case Study**

473

474 As an initial motivational case study to explore the expected benefits of this approach,  
475 only one key performance indicator (KPI) is applied to evaluate the quality of allocation:  
476 total cost. This initial deterministic optimization framework (only objective function and  
477 demand balance, i.e. LP) is applied to a real industrial case; Syngenta AG provided real  
478 data on two crops representing 200+ products to be allocated to 20+ growing regions and  
479 10+ growing areas on one continent. The optimal allocation plans are then compared with  
480 the original seed production plans generated by Syngenta. The results of the optimization  
481 contrasted with the original allocation plans of Syngenta can be revealed and divided into  
482 two aspects: reductions in cost and improvements in planning process efficiency.

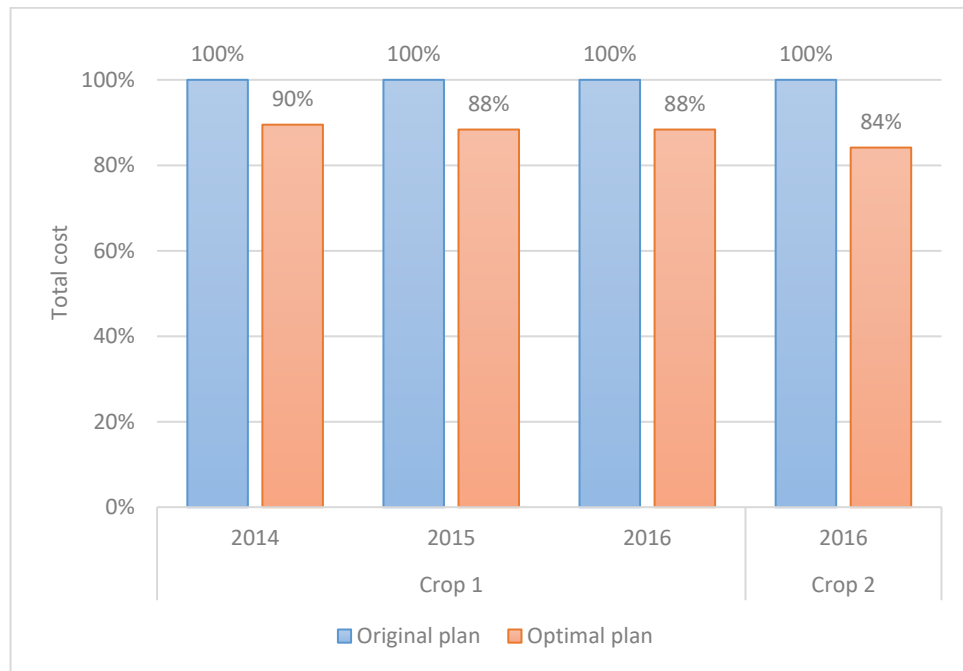

483

#### 484 *Cost Reductions*

485

486 The initial model can be used as either the case to quantify the value of optimization or a  
487 starting point for the implementation of a more detailed deterministic model. Taking the  
488 original allocation plans for the two crops selected in Syngenta as examples, the  
489 following reductions in cost can be observed for total cost:

490  
491

492

493 Fig. 1 Comparison between original and optimal plan

494 For confidentiality reasons, the total cost calculated by the original plan (developed  
495 manually by experts) value has been used as a normalization factor, but it can be seen that  
496 in terms of percentage, 10% - 16% savings have been achieved in total cost. These  
497 savings are equivalent to 5 to 10 million US dollars per year for the regional level case  
498 study. The major sources of this cost savings are the better use of land, balancing cost,  
499 yield and availability for over 100 varieties in 20 regions.

### 500 *Efficiency of planning*

501

502 According to the experience of several industry specialists in Syngenta, it previously took  
503 one month to generate one allocation plan. By using mathematical programming, around  
504 10 hours is used to set up the model and less than a second is needed to generate the plan  
505 presented in Fig. 1 using a standard laptop with guarantee of optimum. In other words,

506 the implementation of mathematical programming in seed production planning can  
507 dramatically boost the efficiency of the entire process.

508

### 509 **Case Study I: Deterministic Model**

510

511 The data for two of major product families of Syngenta have been tested for the pilot  
512 industrial implementation of the complete deterministic model. Since similar benefits can  
513 be obtained from both products, only the results for one type of crop in 2014 with 100+  
514 hybrids, 100+ male varieties, 20+ growing regions and 10+ growing countries are  
515 introduced in this paper. In order to present the business value of the model, KPIs are  
516 defined before the execution of optimization. Only the total cost and total land usage are  
517 presented as KPIs in this section for the purpose of simplification.

518 In the previous subsection, the initial optimization model with only the demand balance  
519 constraint was tested using real world data from Syngenta. In this section, all the  
520 additional constraints described previously have been integrated into the model and the  
521 corresponding production plans have been generated and analysed in detail. Similarly as  
522 for the preceding industrial case study, all the solutions are compared with the original  
523 seed production plan from Syngenta. Moreover, the preference and variability constraints  
524 have been analysed separately. With respect to product groups defined in this study, only  
525 three groups are considered: New, Mature and Declining. The new products are regarded  
526 as the most important products with the objective of maximizing stability regardless of  
527 any additional cost, while the production cost of the declining products should be  
528 minimized with lowest production priority regardless of stability in production. The  
529 mature products lie between new and declining products with an objective of minimizing  
530 total cost with reasonable levels of stability.

531 All the additional constraints are applied to improve the practicality and applicability of  
532 the seed production planning; however the most appropriate combinations of constraints  
533 applicable to each product as well as each year will be highly dissimilar and should be  
534 specified by the company at the time of planning. In this case study, all the basic  
535 constraints introduced previously are incorporated while the risk constraints have been  
536 tested separately through the following combinations.

537 Table 1 - Combinations of constraints

Scenario	Constraints
----------	-------------

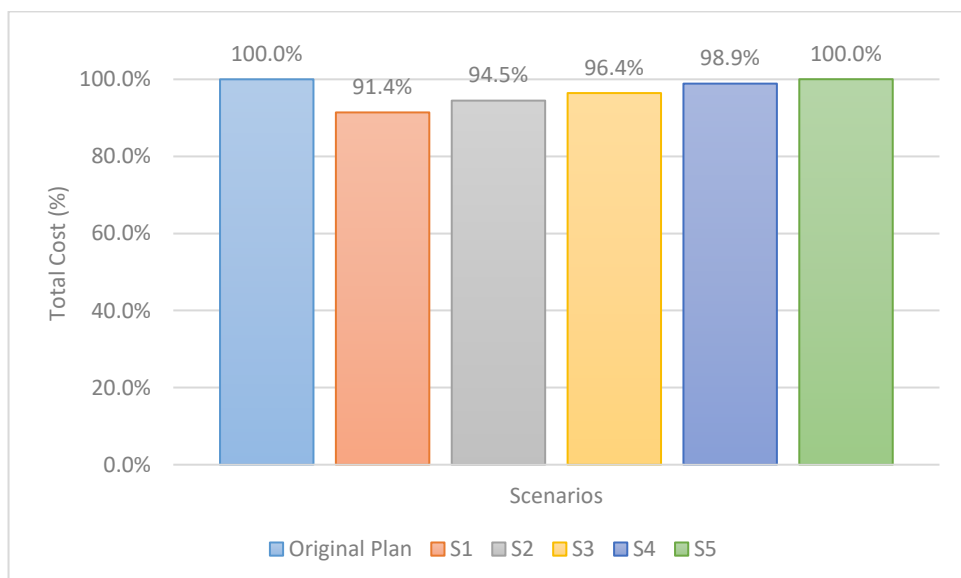

S1	Basic constraints
S2	Basic constraints + Preference constraint (Average 2.50)
S3	Basic constraints + Preference constraint (Average 2.25)
S4	Basic constraints + Variability constraint (New Group Average 0.25)
S5	Basic constraints + Variability constraint (New Group 0.25, Mature Group 0.35)

538

539

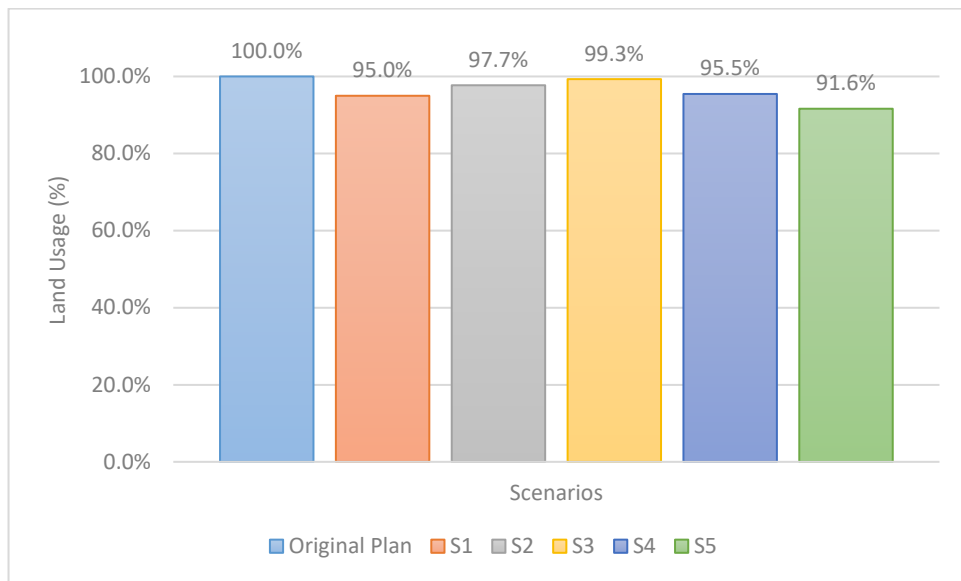

540 The constraints included in the basic constraints set are demand balance, regional level  
541 land availability, existence of land allocation, biological constraint, distribution limit and  
542 commercial importance of the products (only minimum number of production  
543 regions/countries). In **S2** and **S3**, the maximum average preferences for each seed product  
544 family are set at 2.50 and 2.25 respectively. In **S4**, only the overall average variability  
545 ( $MaxTotalVariability_k$ ) of the new group is constrained at 0.25, while both the overall  
546 average variability of the new group and the mature group have been constrained at 0.25  
547 and 0.35 respectively in **S5**.

548 In order to maintain consistency with the original planning process from Syngenta, the  
549 minimum and maximum land availabilities are defined by the actual amount of contracts  
550 assigned by Syngenta. Since these contracts are assigned based on preceding experience  
551 instead of any optimization, there are some extra limitations from these contracts. In spite  
552 of such additional restrictions, the seed production planning process can still be improved  
553 significantly as shown in Fig. 2 and Fig. 3. Note that all the results presented are  
554 normalised using data from the original plan from Syngenta to preserve confidentiality.

555

556 Fig. 2 - Comparisons of total cost

557

558 Fig. 3 - Comparisons of total land usage

559 Without any explicit limitation on risk, the use of deterministic optimization can save at  
560 least 8.6% of cost and 5% land usage even with additional subjective restrictions (through  
561 manually defined minimum land availability). All these savings represent a significant  
562 increase in profitability and sustainability of the company since the implementation of  
563 optimization can not only reduce the cost in production and land usage but also provide  
564 the possibility to easily transfer any business information or requirement to the  
565 production plan instantaneously.

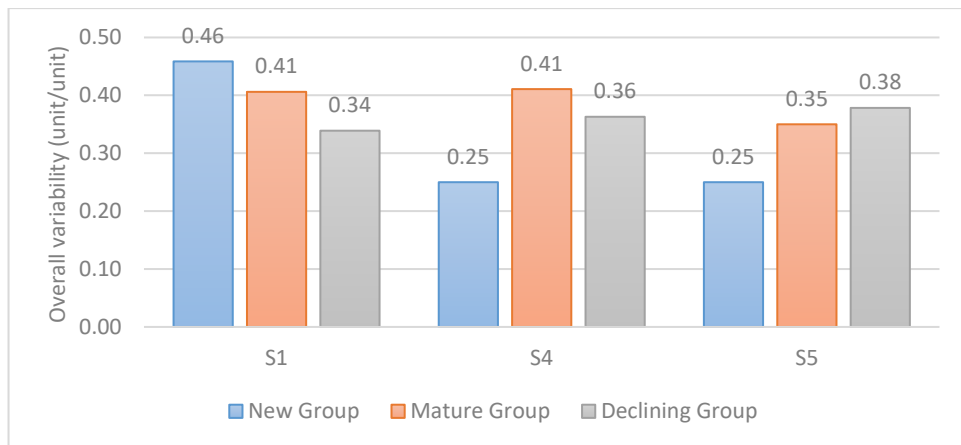

566 In terms of the risk constraints, the impacts and drawbacks of preference and variability  
567 constraints are already discussed previously thus they will not be specifically discussed in  
568 detail in this case study.

569 The addition of preference constraints further restricts the feasible range for selection and  
570 therefore reduces the savings compared with the original seed production plan.

571 Meanwhile, a slight change in constrained average preference index can lead to a large  
572 deviation in both total cost and land usage. Even though the preference index is unable to  
573 quantify precisely the risk associated with seed production, it provides an approach to  
574 evaluate the effect of the risk in case of limited access to accurate statistical information,  
575 e.g. the predicted yield distribution.

576 Similarly as for the preference constraint, the total cost increases with increased  
577 limitations on variability, however the user may also prioritise the stability due to its  
578 ability to quantify the risk with a practical interpretation.

579

580 Fig. 4 - Overall variability for different sales groups

581

582 Although the savings in cost gradually diminish as the restrictions on stability increase,  
 583 the robustness of the allocation plans also increases. Without any limitation on variability,  
 584 the new product group would experience the highest variability due to the relatively low  
 585 maturity in technology and the declining product group would experience much lower  
 586 levels of variation due to its higher maturity and predictable yields. However the primary  
 587 target is to obtain lower variability in the new group. The implementation of this  
 588 variability constraint enables satisfaction of this difficult requirement. However, it is not  
 589 straightforward to quantify the commercial benefits in the improved stability through the  
 590 variability which represents the maximum ratio of deviation compared with demand.  
 591 Hence, a stochastic model is introduced to quantify better the direct benefits brought from  
 592 the improved stability in the next section.

593

594

## 595 **Case II: Stochastic Optimisation Model**

596

597 The stochastic model is implemented with statistically simulated yield distribution data of  
 598 one type of crop from Syngenta AG. The yield distribution itself is generated based on  
 599 historical data and a statistical approach, but the details of distribution generation are not  
 600 discussed as they are beyond the scope of this study. Even though the results stated here  
 601 are only for insights into the benefits of stochastic optimization, the implications are  
 602 already extremely valuable and the method is particularly attractive to implement at full  
 603 scale.

604 Since the purpose of this case study is to evaluate the value of stochastic optimization and  
605 the total production volume is uncertain due to uncertain yield, total cost and total  
606 production volume are used as the main KPIs. Additionally, the cost per bag is illustrated  
607 as an effective indicator of the effectiveness of seed production planning.

608 All the yield distributions (for all the hybrid and growing region combinations) have been  
609 approximated by three scenarios: 20<sup>th</sup> percentile, 50<sup>th</sup> percentile and 80<sup>th</sup> percentile. These  
610 scenarios are represented as lower bound, mean and upper bound respectively in the  
611 following figures.

612 The size of this test case is similar to the previous one, which considered 100+ hybrids,  
613 100+ male varieties, 20+ growing regions and 10+ growing countries.

614 The penalty costs of both overproduction and shortage are approximated in this case  
615 study, and they should be replaced by practical commercial penalties in an actual  
616 implementation of the stochastic model in the decision support tool by the industrial  
617 collaborator.

#### 618 *Improvement in robustness*

619

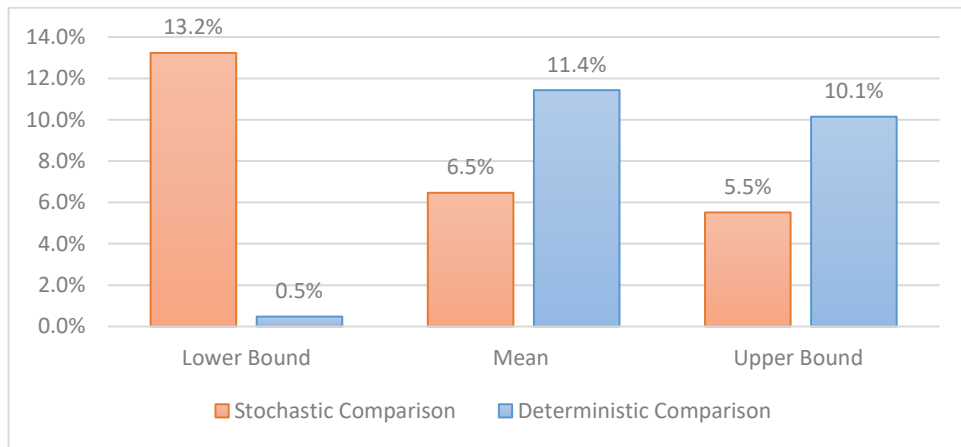

620 Since the land allocation plan is determined much earlier than the actual harvesting, all  
621 the scenarios are actually based on the same land allocation plan (i.e. the first stage  
622 variables) and the analysis is undertaken to illustrate the differences in performance  
623 within each scenario. Although the land allocation remains the same for all scenarios, the  
624 processing cost, transportation cost and the production volume are different due to the  
625 variations in uncertain yield, i.e. the total cost, total production and cost per bag will be  
626 dissimilar in various scenarios.

627 In order to compare the deterministic and stochastic solutions, various values of yield  
628 within each scenario are applied to simulate total cost, production units and cost per unit  
629 separately under each scenario.

630 The comparisons of total cost savings, total production savings and cost per unit savings  
631 compared with the original plan from Syngenta between the deterministic solution and  
632 stochastic solution are presented in Fig. 5, Fig.6 and Fig.7 respectively.

633 In the cases where “Mean Yield” or “Upper Bound Yield” are realised in practice, the  
634 cost savings generated by the deterministic solutions will be more significant. However,  
635 if the actual yield is closer to the “Lower Bound Yield”, the stochastic solution could  
636 potentially lead to 13.2% savings in cost while only 0.5% savings against the default plan

637 can be achieved by the deterministic solution, demonstrating the benefits of implementing  
 638 stochastic optimisation model under yield uncertainty.

639

640 Fig. 5 – Total cost comparison between deterministic and stochastic solutions

641

642 Considering the purpose of production, it should be as close as possible to the demand in  
 643 all possible scenarios. Although the stochastic solution indicates slight over-production in  
 644 the case of “Mean Yield”, less shortage and overproduction are expected in the cases of  
 645 “Lower Bound Yield” and “Upper Bound Yield” respectively.

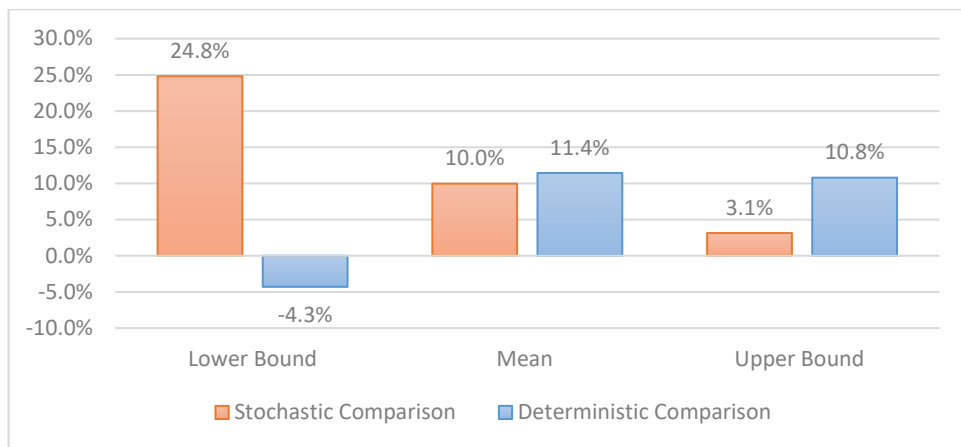

646

647 Fig. 6 – Total production comparison between deterministic and stochastic solutions

648

649 To integrate the influences from total cost and total production, the cost per bag is  
 650 calculated. It presents a similar trend as shown for total cost while the differences in the  
 651 lower bound scenario have increased to 24.8% in the stochastic solution compared with -  
 652 4.3% in the deterministic solution.

653 From the company’s perspective, the robustness of production is much more important  
 654 than possible benefits from any single scenario as reliabilities and predictability of risk  
 655 are always more critical for them as part of managing uncertainty in operations.

656

657 Fig. 7 – Cost per bag comparison between deterministic and stochastic solutions

658

659 In summary, the risk in production can be effectively balanced by the implementation of a  
 660 stochastic model. Although the performance of a deterministic model can be better in  
 661 certain possible future scenarios, the improved robustness of the solution presented by the  
 662 stochastic model is more important for practical application due to unpredictability of the  
 663 future yields.

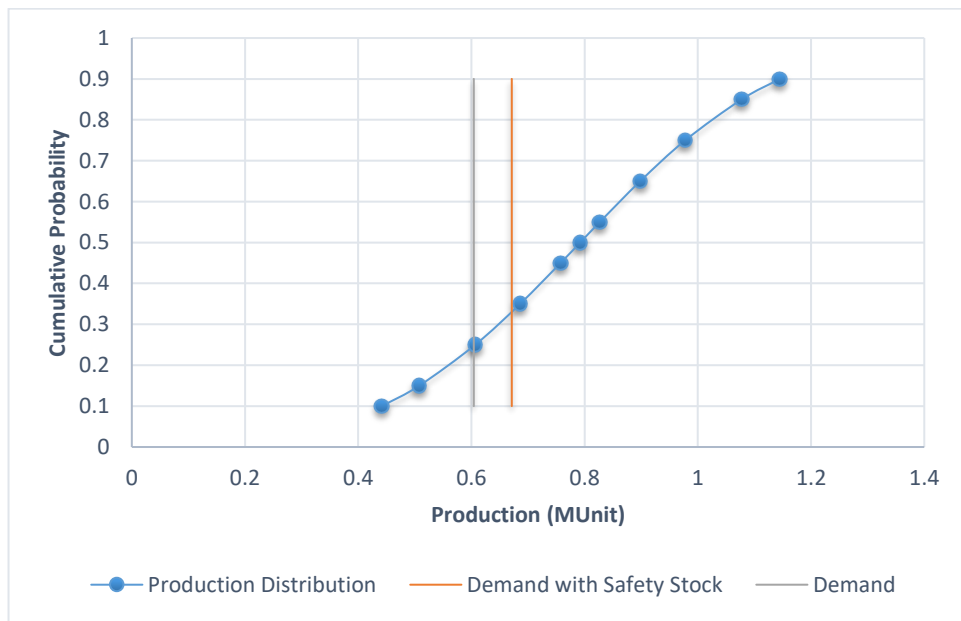

664 *Adjustable multiple objectives*

665 In terms of the multiple types of sales targets, products with various degrees of  
 666 importance are simultaneously optimized with differentiated objectives. The sales group  
 667 concept defined in the previous case study is applied to meet the specified business  
 668 requirements for different sales groups. Since the statistically simulated yield distribution  
 669 mentioned previously can only predict actual yield distribution with a limited level of  
 670 accuracy, 11 scenarios are applied to increase the accuracy of the distribution in the  
 671 stochastic model without overfitting of input data (due to limited level of yield prediction  
 672 accuracy). In other words, 11 scenarios are used to estimate the continuous yield  
 673 probability distribution: 5<sup>th</sup> percentile, 15<sup>th</sup> percentile, 25<sup>th</sup> percentile, 35<sup>th</sup> percentile, 45<sup>th</sup>  
 674 percentile, 50<sup>th</sup> percentile, 55<sup>th</sup> percentile, 65<sup>th</sup> percentile, 75<sup>th</sup> percentile, 85<sup>th</sup> percentile  
 675 and 95<sup>th</sup> percentile.

676 For the “new” group, the aim can be summarized as minimizing the probability of  
 677 shortage regardless of any extra cost or overproduction. Similarly, the objective of the  
 678 “declining” group is to minimize the overall cost and probability of overproduction,

679 where a certain level of shortage is acceptable. Regarding the “mature” group, the target  
 680 can be identified as the minimal expected total cost with a limited level of shortage and  
 681 overproduction. Based on the model introduced previously, the probability of shortage  
 682 and overproduction can be manipulated through modifying the tuneable penalty cost for  
 683 overproduction and shortage.

684 The different objectives from various sales groups can be met simultaneously through  
 685 differentiating various penalty costs. The following figures illustrate an example of the  
 686 production distributions of different groups within one optimization model.

687

688 Fig. 8 - New group cumulative production probability distribution

689

690

691 Fig. 9 - Mature group cumulative production probability distribution

692

693

694 Fig. 10 - Declining group cumulative production probability distribution

695

696

697 Fig. 11 - Total cumulative production probability distribution

698

699 The production volumes indicated in Fig.8 – Fig.11 are all based on simulated data  
700 without any indication of the actual production volumes in Syngenta AG.

701 Compared with the risk constraint in the deterministic model, the probabilistic  
702 distributions of production can directly quantify the value of improved stability through

703 probability, i.e. a lower probability of shortage indicates a lower risk or higher robustness.  
704 When it comes to the trade – off problem between stability and cost, the model itself  
705 provides the flexibility to modify the balance between these two criteria while the final  
706 decision can be made by decision – makers in the company through incorporating the  
707 conditions from all the other aspects of the business at the time of actual planning.

708

## 709 **Conclusions**

710

711 In this paper, models for deterministic MILP and two – stage stochastic optimization are  
712 proposed for a real – world regional level seed production planning problem. The  
713 objective function is to minimize the overall cost including growing, processing and  
714 transportation cost. The demand balance, land availability, land allocation, biological  
715 constraints, distribution limitations and the commercial importance of different product  
716 groups have been taken into account as constraints. The deterministic model covers all  
717 the basic constraints together with the risk constraints to evaluate the effect of the risks in  
718 production and forms the basis for a toolkit used by the industrial partner. The stochastic  
719 model incorporated uncertainty in yield to optimize the effects from uncertain  
720 information.

721 To conclude the impacts from this research, this study addresses the research gap in the  
722 application of mathematical optimization in the seed industry with a focus on seed  
723 production planning at a regional level. It enables a transition from an experience-based  
724 approach in seed supply chain planning to a mathematical programming-based approach  
725 in industry. Quantitatively through industrial continent – wide case studies of the seed  
726 products in Syngenta, the model can save up to 16% in overall cost as well as 9% in total  
727 land usage, while up to 24.8% in cost per bag can be saved in the future by considering  
728 uncertainty. Moreover, the efficiency of planning can be boosted significantly by  
729 reducing the time used to generate a land allocation plan from one month to a few  
730 minutes.

731 Future research directions include global scale seed production allocation optimization at  
732 the field level with additional implementation of multi-objective optimization and links to  
733 harvest and production process scheduling.

## 734 **Acknowledgement**

735

736 The authors would like to thank the Centre for Process System Engineering and Syngenta AG for  
737 their support for this research.
