ABSTRACT
Quasar pairs are either physically distinct binary quasars or the result of gravitational lensing. The majority of known pairs are in fact lenses, with a few confirmed as binaries, leaving a population of objects that have not yet been successfully classified. Building on the arguments of Kochanek, Falco & Muñoz, it is shown that there are no objective reasons to reject the binary interpretation for most of these. In particular, the similarity of the spectra of the quasar pairs appears to be an artefact of the generic nature of quasar spectra. The two ambiguous pairs discovered as part of the Large Bright Quasar Survey (Q 1429+053 and Q 2153+0256) are analysed using principal components analysis, which shows that their spectral similarities are not greater than expected for a randomly chosen pair of quasars from the survey. The assumption of the binary hypothesis allows the dynamics, time-scales and separation distribution of binary quasars to be investigated and constrained. The most plausible model is that the activity of the quasar is triggered by tidal interactions in a galactic merger, but that the (re-)activation of the galactic nuclei occurs quite late in the interaction, when the nuclei are within $80 \pm 30$ kpc of each other. A simple dynamical friction model for the decaying orbits reproduces the observed distribution of projected separations, but the decay time inferred is comparable to a Hubble time. Hence it is predicted that binary quasars are only observable as such in the early stages of galactic collisions, after which the quiescent supermassive black holes orbit in the merger remnant for some time.

Key words: galaxies: interactions – galaxies: nuclei – quasars: general – gravitational lensing.

1 INTRODUCTION
A small fraction ($\sim 1$ in 1000) of quasars are observed to have at least one nearby quasar image with essentially the same redshift (e.g., Kochanek 1995; Hewett et al. 1998), and approximately 50 such systems are known in all (e.g., Keeton & Kochanek 1996). Some of the pairs (and all of the higher multiples) are the result of gravitational lensing by intervening mass distributions; some are physically distinct binary quasars. In most cases the correct interpretation is quite clear, even if considerable observational effort was required, but there is a small number ($\sim 20$) of pairs of quasars which cannot be categorized with certainty (e.g., Schneider 1993; Kochanek, Falco & Muñoz 1999a; Peng et al. 1999). These tend to have angular separations of $\sim 3$ arcsec, and in most cases are treated as potential ‘wide separation’ lenses (e.g., Narayan & White 1988; Wambsganss et al. 1995; Mortlock, Webster & Hewett 1996; Park & Gott 1997; Williams 1997). If they are lenses they indicate the presence of a significant and otherwise unknown population of dark objects with the mass of groups or clusters of galaxies (e.g., Kochanek 1995; Hawkins 1997). If they are binaries they are almost certainly the result of enhanced fuelling in galactic mergers or interactions (Djorgovski 1991; Kochanek et al. 1999a).

The arguments in support of both possibilities are summarized in Section 2. In Section 3 principal components analysis is used to objectively test the spectral similarity of several quasar pairs. The binary hypothesis is subsequently adopted for the entire pair population, and the implications for the dynamics of binary quasars are explored in Section 4. The conclusions are summarized in Section 5, together with a discussion of the future observational and theoretical possibilities.

2 KNOWN QUASAR PAIRS
Table 1 lists all known quasar pairs which have not been confirmed as gravitational lenses, in order of increasing right ascension. This list has been compiled mainly from previous lens candidate compilations (Turner 1988; Surdej 1990a,b; Surdej et al.
It is possible that a physical triple or quadruple quasar exists, but this seems very unlikely, as discussed in Section 4.2.2.

2 It is possible, for example, for a lens to have broad absorption features in one of the images, without the other having a similar absorption pattern.

3 It is possible that the broad-line region consists of sheets of plasma only a few metres thick (Blandford & Rees 1991), in which case the two lines of sight are effectively uncorrelated. This possibility is suggested by Q 0151+0448 (Meylan et al. 1990) and Q 2153−2056 (Hewett et al. 1998) which have been classified as gravitational lenses.
implies a comparable or larger population of combined with the knowledge that most quasars are radio-quiet, lensing model for survey magnitude limits of B

If the 11 ambiguous pairs in Table 1 are predominantly lenses, the statistical properties of the sample should match those of the confirmed lenses, and likewise if they are mainly binaries. Their are some potential pit-falls to this approach (e.g., the definition of the samples; the presence of recently discovered pairs, such as Q 0101.8−3012, which may not require the existence of a particularly dark lens) but it is a potentially powerful method.

Kochanek et al. (1999a) used this technique to argue that most of the wide separation (i.e., ∆θ ≈ 3 arcsec) pairs are not lenses for the following reasons. The existence of the OR binaries, combined with the knowledge that most quasars are radio-quiet, implies a comparable or larger population of OR binaries – presumably the majority of the 10 in Table 1. The distribution of the redshifts of the ambiguous pairs is significantly different to that of the confirmed lenses, which is very difficult to account for in terms of lensing (e.g., Williams 1997). The distribution of flux ratios of the pairs and of the confirmed two-image lenses differ greatly (Fig. 1), although neither are consistent with the distribution predicted by a simple, spherical lens model, implying that further investigation is warranted. Lastly, if the pairs are lenses, the absence of a smooth fall-off at larger separations is at odds with most theoretical models that predict wide separation lenses (e.g., Narayan & White 1988; Kochanek 1995).

The statistical objections to the binary hypothesis have been the uncanny similarities of the spectra of the pairs (which is addressed in Section 3) and the high number of pairs at such small separations (relative to the predictions of the generic quasar–galaxy correlation function). However, Kochanek et al. (1999a) showed that the number of pairs observed was consistent with the number expected from the observed small-scale quasar–galaxy correlation function. Further implications of this are explored in Section 4.

![Figure 1](https://academic.oup.com/mnras/article-abstract/309/4/836/1086308)

**Figure 1.** A cumulative plot of the magnitude differences, ∆m, between the possible lensed quasar pairs (dashed line), and all known two-image lenses, both with (upper solid line) and without (lower solid line) the known arcs and rings (which are generally treated as having ∆m = 0). The two smooth solid curves show the distribution predicted by a simple lensing model for survey magnitude limits of B = 19 (upper line) and B = 21 (lower line).

3 SPECTRAL SIMILARITIES OF QUASAR PAIRS

The spectra of many of the pairs do appear unusually alike, but, before this can be regarded as an objection to the binary hypothesis, it must be shown quantitatively that they are significantly more alike than those of randomly chosen quasars.3

There have been several attempts to implement this sort of test, but the limitations of the data have proved critical in most cases. Turner et al. (1988) found that the the emission-line shapes of Q 1634+267 A and B were more similar to each other than they were to those of another quasar of comparable luminosity and redshift, although the use of only a single comparison object limited the strength of the conclusions. Peng et al. (1999) found that the CIV equivalent widths and continuum slopes of 14 pairs (all those in Table 1 bar Q 0101.8−3012 and Q 1208+1011) were more alike than over 97 per cent of comparable random quasar samples, implying that the apparent spectral similarities are real. Lastly, Hawkins (1997) found that the colours of the two components of Q 2138−431 and Q 2345+007 were closer than expected, when compared to those of ∼10 other quasars with similar redshifts. However the control quasars represent a heterogeneous sample, which can only increase the relative similarity of the colours of the pairs. This illustrates why such relative tests are better at demonstrating pairs can be binary objects. In a related investigation, Small, Sargent & Steidel (1997) showed that the differences between the component spectra of Q 1634+267 and Q 2345+007 were no larger than the temporal variations in other quasars. Hence these pairs are consistent with being lenses, despite the differences in their spectra. However this represents only a necessary condition, and is not a sufficient condition for the lensing interpretation. The choice of experiment is probably an artefact the greater interest in finding lenses.

The analysis that follows is directed towards determining whether the two ambiguous quasar pairs in the Large Bright Quasar Survey (LBQS) are consistent with being binaries. The data is described in Section 3.1 and the method of comparison discussed in Section 3.2. The results and interpretation are given in Section 3.3.

3.1 Quasar pairs in the Large Bright Quasar Survey

The LBQS is a sample of 1055 quasars with $m_B \approx 18.5$, selected spectroscopically and without any reference to morphology (Hewett, Foltz & Chaffee 1995). Owing to both its size and its well-characterized selection effects, it is an excellent source of data for studying the similarities and differences between quasar spectra.

As part of the survey, there was a systematic search for companions within ∼10 arcsec of each quasar. The companion search has sufficient dynamic range (∆m = 3.5) to easily pick out most secondary lensed images, and also to detect potentially dimmer binary companions. The search has yielded three pairs so far (listed in Table 2), and it is ‘unlikely that further pairs will be identified’ (Hewett et al. 1998). Q 1009−0252 (Hewett et al. 1994) is a confirmed lens; Q 1429−0053 (Hewett et al. 1989) is a reasonable lens candidate; and Q 2153−2056 (Hewett et al. 1998)

---

3 Even then, there are some reasons to think that binaries may have similar spectra due to their common environment and formation time (Peng et al. 1999). However it is difficult to see how either could influence the localized velocity fields that are responsible for the emission-line shapes.
is probably a binary quasar. The spectra of all three pairs, taken concurrently in each case, are shown in Fig. 2, and it is clear that there are significant differences between the primary and companion of both Q 1009−0252 (the lens) and Q 2153−2056. However, a more quantitative, and hence objective, means of testing the similarity of the spectra is needed to proceed further.

3.2 Comparison of quasar spectra

The most common method of analysing spectra (aside from visual inspection) is to measure the properties of individual features, such as emission lines and continuum properties. The weakness of this approach is that the classification is usually subjective at some level.

It is preferable to use a completely quantitative method, such as principal components analysis (PCA; Whitney 1983; Murtagh & Heck 1987; Mittaz, Penston & Snijders 1990). PCA can be used on pre-determined features, but, for the reasons given above, it is more powerful to perform PCA on the raw spectra. This ‘spectral’ PCA has the advantages that it is a completely objective analysis, uses all the available data, and is adept at dealing with low signal-to-noise ratio spectra. With each spectrum treated as a vector in a multi-dimensional space, the sample of spectra represents a spherical distribution of points that is essentially a hyper-sphere of PCs usually (i.e., if the PCA is successful) leaves a condensed, the subsequent components. The subtraction of only the first few PCs, each spectrum is still a multi-dimensional vector. The data can be further compressed by defining a metric in the PC space. The PCA naturally scales the variance in each component with its relative importance, so a simple Euclidean metric is chosen. The difference, \( D \), between the spectra of two quasars A and B is then given by

\[
D_{AB} = \left[ \sum_{n=1}^{n_{\text{max}}} (C_{A,n} - C_{B,n})^2 \right]^{1/2},
\]

where \( C_{A,n} \) and \( C_{B,n} \) are the coefficients of the \( n \)th principal component of spectra of A and B, respectively, and \( n_{\text{max}} \) is the highest component used. The latter does not have an appreciable effect on the results, as long as the first few components are included, so \( n_{\text{max}} = 4 \) was used.

Two sets of \( D \)-values were created for each sample: the differences between all the spectra in the sample; and the differences between each of the primaries of the pairs and the rest of the sample (which determines the fraction of spectra in the sample that are closer to the primary in question than its companion). The resultant cumulative plots are shown for sample 1 and sample 2 in Figs 5 and 6, respectively.

3.3 Implications for the quasar pairs

The two components of the confirmed lens, Q 1009−0252, are clearly different. This is not unexpected – as discussed in Section 2.1, there are a number of reasons why lensed spectra need not be

| Name | Status | \( m_A \) | \( m_B \) | \( \Delta m \) | \( z \) | \(|\Delta v|\) | \( \Delta \theta \) | Ref. |
|------|--------|---------|---------|----------|------|--------|---------|-------|
| Q 1009−0252 | Lens | \( V = 17.9 \) | \( V = 20.5 \) | 2.6 | 2.74 | 150 ± 200 km s\(^{-1}\) | 1.5 | 1 |
| Q 1429−0053 | Unknown | \( R = 17.7 \) | \( R = 20.8 \) | 3.1 | 2.08 | 260 ± 300 km s\(^{-1}\) | 5.1 | 2 |
| Q 2153−2056 | Binary? | \( B = 17.9 \) | \( B = 21.3 \) | 3.4 | 1.85 | 1100 ± 1500 km s\(^{-1}\) | 7.8 | 3 |

‘Status’ summarizes the current evidence concerning the nature of each pair (see Table 1 and Section 2.1.); \( m_A \) and \( m_B \) are the magnitudes of the primary and its companion, respectively; and \( \Delta m \) is the difference between the two (the band is given in the table.); \( z \) is the redshift of the pair; \( |\Delta v| \) is the observed line-of-sight velocity difference; and \( \Delta \theta \) is the angular separation of the two components.

the same. However, this analysis shows that they can actually be less similar than a two spectra chosen at random: Fig. 5 shows that 75 per cent of random pairs are more alike than the components of the lens. However the main difference between the two spectra of Q 1009–0252 is the reddening of the companion spectrum (Fig. 2a), which is probably because of dust along the line of sight to the fainter image (see Section 2.1 and Falco et al. 1999).

The components of Q 2153–2056 are also more dissimilar than those of random pairs. Naively, the lesson of Q 1009–0252 implies that Q 2153–2056 cannot be rejected as a lens on this basis alone. The difference between the spectra of Q 2153–2056 cannot be so readily explained in terms of lensing – indeed it appears that the companion is a broad absorption line quasar, which is only explained simply \(^4\) if they are two distinct objects. This distinction reveals one of the limitations of PCA – there is no physics or plausibility input, and so it cannot tell that some spectral differences (specifically Q 1009–0252) might be owing to dust. In this instance, a continuum fit to the spectra would circumvent this problem. Because of both the spectral differences and the absence of a visible deflector, Hewett et al. (1998) interpret Q 2153–2056 as a probable binary, a conclusion which is confirmed here.

The results for Q 1429–0053 (which is a more probable lens a priori) are more interesting. For the wavelength range covered by sample 1, the components of Q 1429–0053 are more similar than

\(^4\) See Section 2.1 for a complex explanation.
Binary quasars

841, 85 per cent of random pairs. It also appears that Q 1429 2 0053 is a slightly unusual quasar spectrally, and so only 9 per cent of the spectra are more similar to the primary than its companion. The sample results paint a slightly different picture. Q 1429 2 0053 B is no more similar to Q 1429 2 0053 A than a random quasar from the sample. This is despite the fact that Q 1429 2 0053 A is at least slightly unusual — the dashed line and the solid line (representing the whole sample) are quite separated in Fig. 6. Such results are perfectly consistent with Q 1429 2 0053 being a lens (cf. Q 1009 2 0252), but are also perfectly consistent with the two spectra having been drawn at random from the LBQS, and hence consistent with Q 1429 2 0053 being two distinct quasars. However, almost all the difference between the two components of Q 1429 2 0053 can be attributed to the relative strengths of the Lyα/N v complex (appearing at ~1230 Å in Fig. 2b); the equivalent widths differ by ~50 per cent. The possibility of microlensing of the secondary image (see Section 2.1.) means that the lens interpretation is still possible, although the macrolensing flux ratio this would imply (Δm ~ 3.5) is very unlikely a priori (e.g., Fig. 1).

There are several potential systematic errors which, whilst they do not affect the above conclusions, are important in principle. The samples covered a wide redshift range, possibly increasing the spread in the spectra of the samples; this could result in a true binary being rejected, but could not result in a lens being wrongly classed a binary. Another potential bias that is unimportant is the faintness of the companion images in these pairs — lower luminosity quasars might have different spectra. If the pairs are lenses this is clearly irrelevant, as they are not intrinsically so faint. If they are binaries, any bias that might make the spectra appear more dissimilar is acceptable, even desirable.

The main source of random uncertainty is the low quality of the spectra of companions (despite the fact that PCA is adept at analysing low signal-to-noise data), which is simply a function of their faintness (Table 2). Several hours of observation on a 10-m class telescope would yield companion spectra of better quality than the current primary spectra.
4 DYNAMICS OF BINARY QUASARS

If all the quasar pairs listed in Table 1 are physical binaries, there are far too many to represent a simple a small-scale manifestation of quasar clustering (Djorgovski 1991). The fairly natural conclusion (Djorgovski 1991; Schneider 1993) is that any close quasar pairs are the result of increased nuclear activity in interacting galaxies. Kochanek et al. (1999a) showed that the number of binaries matches the number expected from the quasar-galaxy correlation function at small scales. Henceforth, all the pairs in Table 1 are treated as physical binaries, and the merger model is also adopted. The sample of pairs can then be used to constrain the distribution of physical separations (Section 4.1), and also to investigate the formation and evolution of binary quasars (Section 4.2).

4.1 Physical separations

The projected separations of the quasar pairs can be inferred for a given cosmological model (Section 4.1.1), but some method of inversion is required to obtain the distribution of physical separations. A random deprojection is explored in Section 4.1.2 and a simple orbital model is discussed in Section 4.1.3.

4.1.1 Cosmological models

The projected separations of the pairs are given by \( R = \Delta \theta \cdot d_\Delta(0, z) \), where \( d_\Delta \) is the angular diameter distance, and so \( R \) varies with the cosmological model (and also within a model, owing to weak lensing). Three models are used: the Einstein-de Sitter (EdS) model (\( \Omega_m = 1 \) and \( \Omega_\Lambda = 0 \)); a low-density model (\( \Omega_m = 0.3 \) and \( \Omega_\Lambda = 0 \)); and a low-density, spatially flat model (\( \Omega_m = 0.3 \) and \( \Omega_\Lambda = 0.7 \)), where \( \Omega_m \) is the ratio of the current density of the universe to the critical density and \( \Omega_\Lambda \) is the similarly normalized cosmological constant (e.g., Carroll, Press & Turner 1992). The \( \sim 10 \) per cent error in Hubble’s constant (taken to be \( H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1} \) here) does not contribute significantly to the uncertainty in \( R \).

4.1.2 Random deprojection

The problem of deprojection – effectively obtaining three dimensional information from a two-dimensional image of the sky – is an old one, with a number of different partial solutions (e.g., Courant & Hilbert 1962; Gerhard & Binney 1996). The problem at hand is to obtain a probability distribution of the physical separation, \( dp/\text{d}r |_R \), given an observed projected separation, \( R \). A Bayesian approach is adopted whereby the separation vector, \( \mathbf{r} \), is considered to be randomly-oriented, a posteriori. Mathematically, \( dp/\text{d}i = \sin(i) \), where \( i \) is the (inclination) angle between \( \mathbf{r} \) and the line-of-sight. It is normalized for the range \( 0 \leq i < \pi/2 \), and the projected separation is given by \( R = r | \sin(i) | \). From this, a change of variables yields

\[
\frac{dp}{dr} \bigg|_R = \left\{ \begin{array}{ll}
0, & \text{if } r < R; \\
16 \frac{R^3}{\pi r^4} \sqrt{1 - \frac{R^2}{r^2}}, & \text{if } r \geq R,
\end{array} \right.
\]

where the final distribution is also normalized to unity, and has an expectation value of \( 16/(3\pi R) \), assuming \( R > 0 \).

Convolving \( dp/\text{d}r |_R \) with the data gives an approximation to the physical separation distribution of the binary quasars, the differential and cumulative forms of which are shown in Fig. 7. This ‘random deprojection’ shows a tail of pairs with quite large separations and a possible paucity of small separation pairs. (The one pair with \( r \approx 10 \text{ kpc} \), Q 1208+1011 is a probable lens; if it were confirmed as such, the small separation ‘hole’ would be quite clear.) Any hole cannot explained by selection effects, as there are a large number of lenses with angular separations \( \sim 1 \text{ arcsec} \), implying that any such binaries would have been found. Kochanek et al. (1999a) showed that dynamical friction (Section 4.2.3) can account for the hole, although the inferred separation distribution (linearly rising with \( r \)) is otherwise quite different from the approximately exponential fall-off apparent in Fig. 7. Some clues as to the nature of small separation binaries...
might be given by the discovery of three possible binaries in a sample of ~100 BL Lacs (Scarpa et al. 1999). The frequency of these pairs is far too high to be explained in terms of gravitational lensing by galaxies, but the binary interpretation is no more comfortable. It would require not only that a few per cent of BL Lacs are binaries, but that the optical jets of the companion BL Lacs are parallel.

4.1.3 Orbital models

An approach almost opposite to the random deprojection used in Section 4.1.2 is to assume an orbital model for the binaries, and fit the resultant distribution of projected separations to the data. The paths of two quasars in a pair of merging galaxies is undoubtedly complex, but a natural first approximation is to assume that they are in decaying elliptical orbits. However averaging over the random orientation removes most of the effects of ellipticity, so circular orbits can be used in general (Mortlock 1999). The main difference was in the radius of closest approach, which may be relevant to the activation of the quasars (Section 4.2.2). The existence of the outer cut-off of between 50 kpc and 100 kpc is confirmed, independent of the distribution of separations used. The putative inner cut-off is less well constrained, and, assuming a distribution of separations used.

4.2 Physical processes

If binary quasars are the result of galactic collisions during which both nuclei become active, the assumption that the systems are bound implies a minimum mass for the systems (Section 4.2.1, and the distribution of physical separations (along with timing arguments) can be used to investigate both the activation and evolution of the pairs (Sections 4.2.2 and 4.2.3, respectively).

4.2.1 Total energy

It is possible that quasars could form in ‘glancing’ collisions (e.g., Noguchi 1987, 1988), but the absence of ‘post-collisional’ pairs with larger separations argues against this for the binary population, implying that they exist in gravitationally bound systems. The minimum possible centre-of-mass frame energy of a pair (obtained by setting the line-of-sight separation and projected velocity difference to zero) is

$$E_{\text{min}} = \frac{M_A M_B \Delta v_{\|}^2}{2} - \frac{G M_A M_B}{R},$$

(3)

where $G$ is Newton’s gravitational constant, and $M_A$ and $M_B$ are the masses associated with the two quasars. Inverting equation (3) and assuming $E_{\text{min}} = 0$ gives the hard lower limit for the mass of a bound system as

$$M_{\text{tot}} = M_A + M_B \geq \frac{R \Delta v_{\|}^2}{2G}.$$

(4)

Fig. 9 shows a scatter plot of the projected separations and velocity differences of all the pairs in Table 1, with the large uncertainties in both $R$ and $\Delta v_{\|}$ clearly important. Despite this, $M_{\text{tot}} \simeq 5 \times 10^{11} M_\odot$ is inferred, confirming that quasars are typically in larger galaxies (Hooper, Impey & Foltz 1997). However using the random deprojection discussed in Section 4.1.2 to account for the projection effects yields a larger (but softer) limit of $M_{\text{tot}} \simeq 2 \times 10^{12} M_\odot$ (Mortlock 1999).

4.2.2 (Re-)activation

It is widely believed that quasars are the active nuclei of galaxies, where gas (and other material) accretes onto a massive central black hole (e.g., Lynden-Bell 1969; Rees 1984). Many galaxies have massive but quiescent black holes at their centres (e.g., Kormendy et al. 1996, 1997), and there are several plausible explanations for how they may begin accreting and become active.
galactic nuclei. One important mechanism appears to be encounters between galaxies, which can result in the formation of a massive black hole (e.g., Rees 1984) or provide fuel to previously quiescent nuclei. This is supported by Hubble Space Telescope (HST) observations which show that the host galaxies of many quasars are distorted (Bahcall, Kirhakos & Schneider 1995a; Boyce, Disney & Bleaken 1999) and that low-redshift quasars are often found to be physically associated with other galaxies (e.g., Yee 1987; Bahcall, Kirhakos & Schneider 1995b; Bahcall et al. 1997) or involved in collisions (Steidel & Sargent 1990). N-body simulations also show that gravitational torques between colliding galaxies can cause gas to flow to their cores, potentially acting as fuel for the central black holes (Barnes & Hernquist 1996). The scales of the in-flows are not great enough to produce new black holes, but are consistent with the re-fuelling model. However, the simulations only predict in-flow to within a few hundred pc of the cores of galaxies, whereas typical quasar accretion discs extend out to only pc scales (Peterson 1997). It is not clear whether dissipation is sufficient to allow the gas to fall further.

The formation of binary quasars is qualitatively consistent with the reactivation process, provided that the progenitors (or their central black holes) are sufficiently massive. The observational result that the activation radius is between 50 kpc and 100 kpc (Section 4.1) implies that quasar formation does not occur until quite late in the collision process. This is consistent with the N-body simulations of Barnes & Hernquist (1996), which showed that gas inflows took some time to occur.

The separation scale of the binaries, together with the requirement of a massive black hole, is also suggestive of the fact that quasars form in larger galaxies. If this is the case, encounters between dwarfs and large galaxies can result in the formation of a quasar, but only collisions between two large galaxies can result in a binary quasar. The fraction of merger-related quasars which are binaries is comparable to the fraction of collisions in which both galaxies have central black holes of \( \geq 10^8 M_\odot \). Assuming a Schechter (1976) mass function for the galaxies, and that \( \sim 20 \) per cent of those heavier than \( M_\odot = 10^{11} M_\odot \) contain large black holes (Matorrian et al. 1998), about 1 per cent of all merger-formed quasars should be in binary systems.\(^5\) Combined with the observation that only 1 quasar in \( \sim 1000 \) is a binary, this implies that about 10 per cent of quasar activity is related to galactic interactions. This is probably an underestimate of the fraction, however, as interactions between two large galaxies are almost certainly more efficient than collisions involving a dwarf galaxy. Further, if quasars all have a dusty torus which is both optically thick and subtends a large fraction of the solid angle around the central engine, both the quasars in a pair must be close to face-on for it to be observed as a binary. Extrapolating from the observation that \( \sim 25 \) per cent of all Seyferts are of Type I (Peterson 1997), 1 in \( \sim 4 \) of all quasars are visible, but only 1 in \( \sim 16 \) binaries are detected as such. It is thus possible that \( \sim 50 \) per cent of all quasars are formed during galactic interactions and collisions.

4.2.2 Evolution

The theoretical and observational evidence discussed in Section

\( \S \) It also implies that only \( \sim 1 \) per cent of multiple quasars should be triples etc., justifying the assumption that all observed triples and quadruples are actually lenses.

4.2.2 is consistent with binary quasars forming during galactic mergers. Once the merger has begun to settle, the quasars can be treated as point-masses moving in a static, isothermal halo. Their orbits slowly decay, as they lose energy and angular momentum through dynamical friction (e.g., Binney & Tremaine 1987), eventually either merging (e.g., Makino & Ebisuzaki 1994) or forming a hard binary that lasts for a Hubble time or more (e.g., Begelman, Blandford & Rees 1980; Rajagopal & Romani 1996). If the quasars have mass \( M = 10^9 M_\odot \) by this stage, and are in circular orbits of speed \( \sqrt[2]{2} \sigma \) (where \( \sigma \) is the velocity dispersion of the halo), the time spent with separation at radius \( r \) is (Binney & Tremaine 1987)

\[
\frac{dr}{dt} = 3.3 \frac{\sigma}{GM \ln(A)} r,
\]

where \( \ln(A) = \ln(2r_0 \sigma^2/GM) \) is the Coulomb logarithm, which characterizes the strength of the interaction, and \( r_0 = 10 kpc \) (Lacey & Cole 1993). Hence \( dr/dt \propto r \), as used in Section 4.1.3 to fit the observed separation distribution. The orbital decay proceeds at a greater rate as \( r \) decreases, potentially explaining the small separation hole (Section 4.1).

The time-scale for the decay, \( t_{DF} \), is found by integrating equation (5) from \( r_{max} \) to 0. Following Binney & Tremaine (1987),

\[
t_{DF} = 4 \times 10^8 \left( \frac{r_{max}}{20 kpc} \right)^2 \left( 200 km s^{-1} \right) \frac{3}{2} \frac{10^9 M_\odot}{M} yr,
\]

where the scale values have been chosen to give the shortest plausible decay time.\(^6\) The dynamical time-scale of the binaries is then close to a Hubble time, and much longer than both the ‘settling’ time of the merged halo (<10\(^9\) yr; Barnes 1992) and the expected quasar lifetime. A black hole of initial mass \( \sim 10^7 M_\odot \) (as implied by dynamical measurements of local galaxies; Kormendy et al. 1996) accreting at the Eddington limit (Peterson 1997) would reach \( \sim 10^{10} M_\odot \) in much less than 10\(^7\) yr. No such massive black holes are observed now (e.g., Kormendy & Richstone 1995), so this places an upper limit on quasar masses and hence their lifetimes. Comparison of the three time-scales implies that binary quasars are short-lived, existing only whilst the host galaxies are actively merging. The most likely explanation for the death of the binaries (and other quasars in mergers) is that the in-flow of gas ceases, probably as the merger becomes more stable. Moreover, by the time the orbits decay owing to dynamical friction, the merging black holes are already quiescent, and the observed binary separation distribution is a random sampling of the chaotic phase of the merging.

If the above model is correct, the hosts of binary quasars should be either distinct (in the case of a ‘new-born’ binary), or, more likely, highly distorted. The host galaxies of MGC 2214+3350 A and B (Muñoz et al. 1998) have been detected by the HST, and in fact out-shine the quasars in the \( H \)-band (Kochanek et al. 1999b). The galaxies show no obvious signs of being distorted, which implies both that their physical separation is considerably greater than their projected separation of \( \sim 20 kpc \), and that the nuclei

6The value of \( r_{max} \) used is half the activation radius inferred in Section 4.1, as it is possible that both quasars orbit the centre of the halo, whence the distance between them is twice their orbital radius. Also, the black holes themselves might start with \( M \ll 10^8 M_\odot \), but they must be associated with most of their eventual mass; hence the choice of the canonical mass.
have only recently become active. Comparable observations – which need not be prohibitively deep – of some of the other ambiguous pairs ought to prove similarly revealing.

5 CONCLUSIONS

Djorgovski (1991) and Kochanek et al. (1999a) have both argued that most of the known wide separation quasars pairs are not the result of gravitational lensing, as summarized in Section 2. However, there have also been some valid objections to the interpretation of the pairs as physical binaries. The strongest was that the spectra of the pairs appear to be very similar. Section 3 consists of a quantitative evaluation of this claim for the three quasar pairs discovered as part of the LBQS, and shows that, despite appearances, none of these pairs can be rejected as binaries on spectral grounds. Extrapolating to the rest of the ambiguous quasar pairs, the simplest conclusion is that they are all binary quasars.

The adoption of the binary hypothesis for the entire population of 16 pairs listed in Table 1 provides a significant data set of binary quasars, and even if some do turn out to be lenses, the statistical properties of the population will not be greatly changed. Assuming quasars are the nuclei of large galaxies, the velocity differences of the pairs are consistent with them belonging to bound systems, which supports the idea that they are part of galactic mergers. Both the orbital and deprojection analyses presented in Section 4.1 suggest that the galactic nuclei become active at separations of between 50 and 100 kpc, depending on the cosmology and the ellipticity of the orbits of the quasars. This is certainly consistent with the scales at which the tides from large galaxies become important. However the time-scales suggested for the orbits of the nuclei to decay are very large – certainly longer than the lifetime of a quasar accreting at the Eddington limit. Indeed it seems probable that the quasars remain active only whilst the host galaxies are merging, in which case most of the binaries should exist in very distorted hosts, and not in a relaxed merger. The observation that the host galaxies of MGC 2214+3550 A and B (Kochanek et al. 1999b) are undisturbed then suggests that this is a very young binary.

Whilst it is clear that the physics of merging galaxies and active galactic nuclei are far from solved, there are also a number of questions that can be answered observationally. Further spectroscopy and radio observations of a number of the quasar pairs should reveal whether they are binaries, although there are also several which are still not classified despite major observational efforts. The nature of the ‘turn on’ radius will be more strongly constrained by the 2 degree Field quasar survey (Boyle et al. 1998), which will include analysis of the nearby companions of $\sim 3 \times 10^5$ quasars. On a longer time-scale, the Sloan Digital Sky Survey (Gunn & Weinberg 1995) will observe $\sim 10^5$ quasars, and is expected to find several hundred lenses and pairs, an order of magnitude increase on the number known presently. Both the lower limits on mass of the host galaxies of the quasars and the constraints on the activation radius could be determined to within $\sim 10$ per cent from such a sample.
