(Dated: May 27, 2021)

Starting with twisted bilayer graphene, graphene-based moiré materials have recently been established as a new platform for studying strong electron correlations. In this paper, we study twisted graphene monolayers on trilayer graphene and demonstrate that this system can host flat bands when the twist angle is close to the magic-angle of 1.16° . When monolayer graphene is twisted on ABA trilayer graphene (denoted AtABA), the flat bands are not isolated, but are intersected by a dispersive Dirac cone. In contrast, graphene twisted on ABC trilayer graphene (denoted AtABC) exhibits a gap between flat and remote bands. Since ABC trilayer graphene and twisted bilayer graphene are known to host broken symmetry phases, we further investigate magic-angle AtABC. We study the effect of electron-electron interactions in AtABC using both Hartree theory, and an atomic Hubbard theory to calculate the magnetic phase diagram as a function of doping, twist angle and perpendicular electric field. Our analysis reveals a rich variety of magnetic orderings, including ferromagnetism and ferrimagnetism, and demonstrates that a perpendicular electric field makes AtABC more susceptible to magnetic ordering.

INTRODUCTION

The observation of strong correlation phenomena in graphene-based moiré materials [1–5] has driven efforts to understand their electronic structure and behaviour. A key prerequisite for the emergence of correlated states are flat electronic bands that give rise to a high density of states (DOS) at the Fermi level. The total energy of electrons in flat bands is dominated by the contribution from electron-electron interactions [6–8], which favors states that break symmetries of the Hamiltonian, opening gaps at the Fermi level to lower the total energy of the electrons. In moiré materials, it is possible to “engineer” a high DOS at the Fermi energy through tuning the relative twist angle to values where very flat electronic bands emerge.

The total number of potential graphene-based moiré materials is extremely large. Consider a system consisting of N graphene layers. Neighboring graphene sheets could either be twisted or not giving rise to 2^{N-1} distinct structures. In principle, this number is further increased when different stacking configurations between the untwisted layers are considered, but in practice the lowest-energy AB-stacking is of most experimental relevance. Finally, these graphitic structures are typically placed on a hexagonal boron nitride (hBN) substrate which can induce an additional moiré pattern [9–11]. Therefore, the space of possible graphitic moiré multilayer structures is vast (even for relatively small values of N) and this space has not yet been fully explored.

Experimental studies on graphene-based moiré materials have focussed thus far on five different systems: twisted bilayer graphene (tBLG) [12–33], twisted double bilayer graphene (tDBLG) comprised of two AB stacked bilayers [34–40], ABC trilayer graphene aligned with hBN (ABC-hBN) [41–43], twisted mono-bilayer graphene (AtAB) [44–46], and different twisted trilayer graphene structures (tTLG) [47–50]. Experimentally, all these systems have been found to exhibit correlated insulator states. Of particular interest are tBLG and tTLG (with an alternating twist angle between each sheet) because - in addition to correlated insulator states - robust superconductivity has been observed in these systems.

All of these systems have been predicted to feature flat electronic bands, which is a good indicator for possible strong correlations (tBLG [51–68], tDBLG [69–75], AtAB [76–79], tTLG [78–83], ABC-hBN [41–43]). In both tBLG [84–88] and tTLG [83] long-ranged electron-electron interactions lead to an additional enhancement of the DOS which increases the robustness of electronic correlations, and could be one reason why robust superconductivity is observed in these materials [89, 90]. In contrast, in tDBLG and mono-bilayer graphene, electric fields are required to further flatten the electronic bands and increase the DOS [34, 35, 37, 38, 44, 45]. Therefore, when investigating new graphitic moiré systems, it is important to investigate both the effect of electron-electron interactions on the band structure in the normal state and the response to external fields.

In this article, we study the properties of twisted mono-trilayer graphene which consists of an untwisted graphene

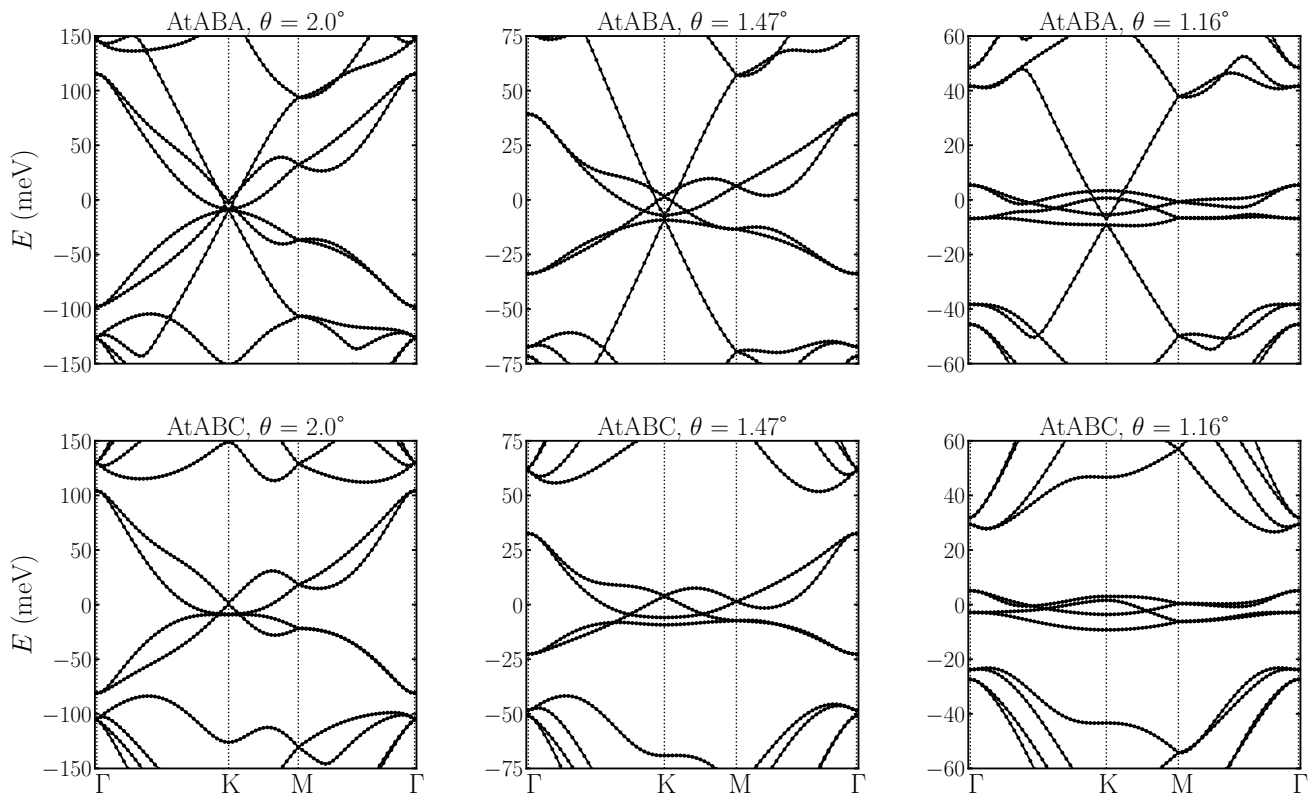

FIG. 1. Tight-binding band structure of AtABA and AtABC at three twist angles: 2.0° , 1.47° and the magic-angle of 1.16° . Additional band structures for other twist angles are shown in Sec. II. of the SM.

trilayer and a graphene monolayer that are twisted relative to each other. For the trilayer, we investigate both ABC and ABA stacking orders, which are both experimentally accessible. For twisted mono-ABC trilayer graphene (denoted AtABC, following the naming convention of Ref. 91), a set of four isolated flat bands emerges at the Fermi level, while in twisted mono-ABA trilayer graphene (denoted AtABA) the four flat bands are not isolated, but are intersected by a dispersive Dirac cone. In contrast to tBLG [84–88] and tTLG [10], long-ranged Hartree interactions have little effect on the band structure. We find that short-ranged Hubbard interactions give rise to a rich magnetic phase diagram as a function of twist angle, doping level and perpendicular electric field that features competing anti-ferromagnetic and ferromagnetic orderings.

RESULTS AND DISCUSSION

Atomic structure

As AtABC and AtABA only contain a single twist angle, the same approach as for tBLG [54] can be used to generate commensurate moiré unit cells [see Sec. I of the Supplementary Material (SM) for details]. We relax

FIG. 2. Density of states (DOS) as a function of energy for AtABC, AtAB and tBLG at a twist angle of 2.0° . The zero of energy is set to the Fermi level at charge neutrality for each system, and the zero in the DOS is at the bottom of the y -axis.

these structures using classical force fields to determine the equilibrium positions of the atoms [92–96]. Specifically, we employ the AIREBO-Morse [97] potential for intralayer interactions and the Kolmogorov-Crespi [98] potential for interlayer interactions, as implemented in LAMMPS [99]. Further details can be found in Sec. I. SM and in Ref. 75.

Electronic Structure

We first calculate the electronic band structure of AtABC and AtABA at different twist angles using an atomistic tight-binding approach, see Fig. 1 and Sec. II. SM for details of the calculation. For both systems, we find that a set of extremely flat electronic bands emerges as the twist angle approaches the magic-angle of 1.16° [100].

At twist angles larger than the magic angle (2.0° and 1.47° in Fig. 1) (top panels), the band structure of AtABA exhibits a set of four flat bands. Two of these form a Dirac cone at the K-point while the other two have a parabolic dispersion near K. At the magic-angle of 1.16° (and also at smaller twist angles) the flat bands no longer form a Dirac cone. The flat bands in AtABA are not isolated in energy from the remote bands because they are intersected by a pair of bands that form a second Dirac cone at K with a larger Fermi velocity, similar to that of monolayer graphene.

Additional insight can be gained by comparing the band structure of AtABA to that of the constituent ABA trilayer. The latter system features a set of parabolic bands which are also intersected by a Dirac cone [101]. This suggests that the addition of the twisted graphene monolayer on top of the ABA trilayer induces the flat Dirac cone (whose Dirac point lies is slightly higher in energy than that of the dispersive Dirac cone) and also modifies the band width of the parabolic bands. Finally, it is also interesting to note that the band structure of AtABA is quite similar to that of twisted trilayer graphene in which the middle layer of an AAA-stacked trilayer is twisted relative to the outer layers [78, 79, 81, 83].

Figure 1 (bottom panels) also shows the band structure of AtABC as a function of twist angle. For this system we also find a set of four flat bands near the Fermi level. Whilst these bands look qualitatively similar to those of AtABA, there are some important differences. As in AtABA, one pair of flat bands form a Dirac cone at K at twist angles larger than the magic angle. The other pair of flat bands, however, now has a cubic dispersion near K, and there is no additional Dirac cone that intersects the flat bands, which are entirely separated from the remote bands in this system near the magic angle.

Again, it is instructive to compare the band structure of AtABC to that of the constituent parts. In ABC trilayer graphene, there is a set of cubic bands near the Fermi level [102], which AtABC retains in the the low-energy dispersion of the isolated flat bands with the twist angle controlling their width. Finally, it is worth noting that the band structure of AtABC is similar to that of twisted monolayer-AB bilayer graphene (AtAB), with the important difference that the dispersion in AtAB is parabolic [45] instead of cubic at the K point, as shown

in Sec. II. of the SM. This difference in the power law of the dispersion has important consequences for the DOS. In Fig. 2, we show the DOS of the flat bands of AtABC, AtAB and tBLG at an angle of 2.0° . All systems have a pair of van Hove singularities at an energy corresponding to a doping level of ± 2 electrons (relative to charge neutrality) per moiré unit cell. The linear dispersion of the tBLG bands close to charge neutrality gives rise to a linear DOS close to the Dirac point where the DOS vanishes. In contrast, for AtAB, the DOS is always finite and exhibits a step-like feature at approximately -5 meV where the parabolic bands touch. Importantly, the AtABC system has an additional van Hove peak arising from the flat bands with a cubic dispersion.

Electron-electron interactions

Based on the tight-binding calculations, we have identified AtABC as a promising candidate for hosting strongly correlated electrons in isolated flat bands. We therefore study the effect of electron-electron interactions in this system. To capture the effect of long-ranged Coulomb interactions, we carry out self-consistent atomistic Hartree theory calculations at integer doping levels per moiré unit cell. However, in contrast to tBLG and tTLG, we find that such interactions only have a negligible effect on the electronic band structure of AtABC, see Sec. III. of the SM for details.

In the absence of Hartree interactions, we consider the effect of exchange interactions. In materials, the exchange is screened by the internal dielectric response of the system [103] and any external screening, for example arising from the presence of nearby metallic gates [104]. As a consequence of screening, the range of the exchange interaction is significantly reduced and we therefore an atomic Hubbard interaction for electrons in the carbon p_z -orbitals [64–68, 83, 105] and calculate the interacting spin susceptibility using the random-phase approximation (RPA) as function of doping, twist angle and value of the Hubbard U parameter. From these results, we identify the critical value of the Hubbard parameter U_c at which the susceptibility diverges [65, 105]. If U_c is smaller than the physical value of the Hubbard parameter, we expect the system to undergo a phase transition into a magnetically ordered state whose spatial structure is determined by the leading eigenvector of the spin response function. In this work, we use a Hubbard value of $U = 4$ eV, which has been shown to be a realistic value of the onsite Hubbard interaction of graphene [106, 107]. Moreover, in Ref. 105, it was shown that $U = 4$ eV for tBLG yields good agreement with the available experimental data. For additional details about the method, see Sec. IV. of the SM and Ref. 65.

Figure 3 shows the structure of various low-energy magnetic states of AtABC at the magic-angle of 1.16° .

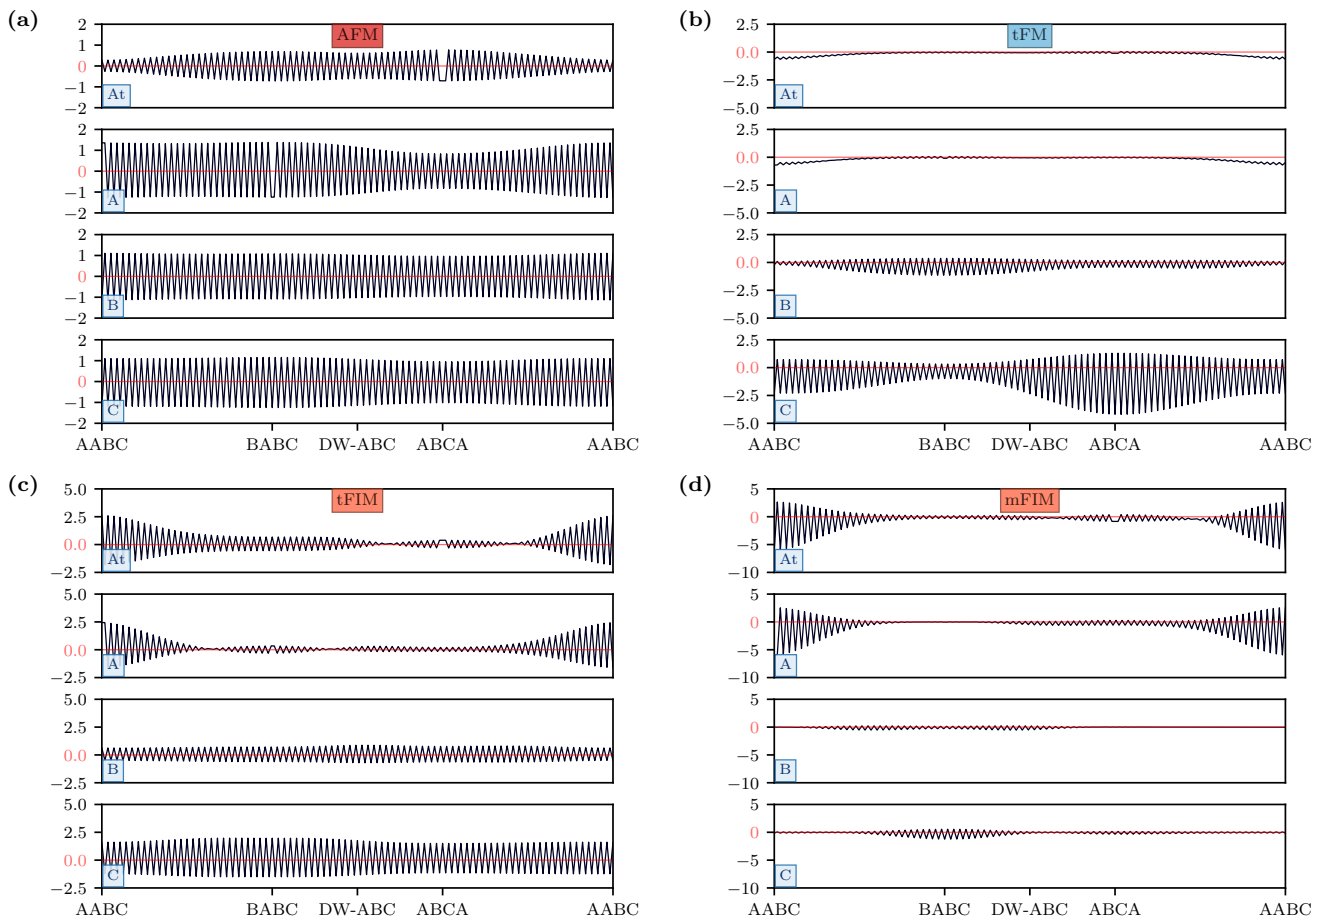

FIG. 3. Line-cut of different layer-resolved magnetic orderings in AtABC along the diagonal of the moiré unit cell at the magic-angle of $\theta = 1.16^\circ$. The local stacking sequence is shown at the bottom of each panel, where DW stands for the domain wall region of the moiré pattern. (a) Anti-ferromagnetic state with mild modulations on the moiré scale. (b) A state with ferromagnetic order in the twisted layers and ferrimagnetic order in the lower layers. (c) A state with modulated ferrimagnetic order in the twisted layers and relatively uniform anti-ferromagnetic order in the lower layers. (d) A state with modulated ferrimagnetic order in all layers.

In each of the plots, we display a normalised eigenvector from the magnetic susceptibility calculations as a function of position along the diagonal of the moiré unit cell (different stacking regions are indicated on the x-axis). Other instabilities are possible, but they are either variations of the ones shown in Fig. 3 with a different nodal structure or mixtures of these orderings.

Figure 3(a) shows an antiferromagnetic (AFM) state which is mostly uniform over the whole AtABC structure and only exhibits a mild modulation on the moiré scale. The magnetization differs slightly in each layer with the largest variations occurring in the graphene sheet that is twisted on top of the ABC trilayer. This layer also exhibits a somewhat smaller magnitude of the magnetization than in the other layers, suggesting that this AFM state is inherited from the AFM state of the ABC trilayer which “spills” into the top layer.

Figure 3(b) shows a state with a modulated ferromagnetic (FM) structure in the top two layers and ferrimag-

netic structure in the bottom two layers. We refer to this ordering as tFM (for twisted FM, as the FM order is found in the twisted layers). In the upper layers the magnetization has peaks in the AABC regions which are separated by a node. A similar state has been found in tBLG [65, 105]. Finally, Figs. 3(c) and (d) show two examples of ferrimagnetic (FIM) states. The state in Fig. 3(c) is mostly AFM with some FIM character and exhibits nodes in the top two layers. We shall refer to this ordering as tFIM (for twisted FIM, as the FIM order is mainly in the twisted layers). The state in Fig. 3(d) is mainly FIM and has significant modulations in each layer. We refer to this state as mFIM (for modulated FIM).

Having described in detail the different types of magnetic states in AtABC, we now discuss the magnetic phase diagram as function of twist angle and doping, denoted by ν for the number of additional electrons/holes per moiré unit cell, shown in Fig. 4(a). Magnetic states

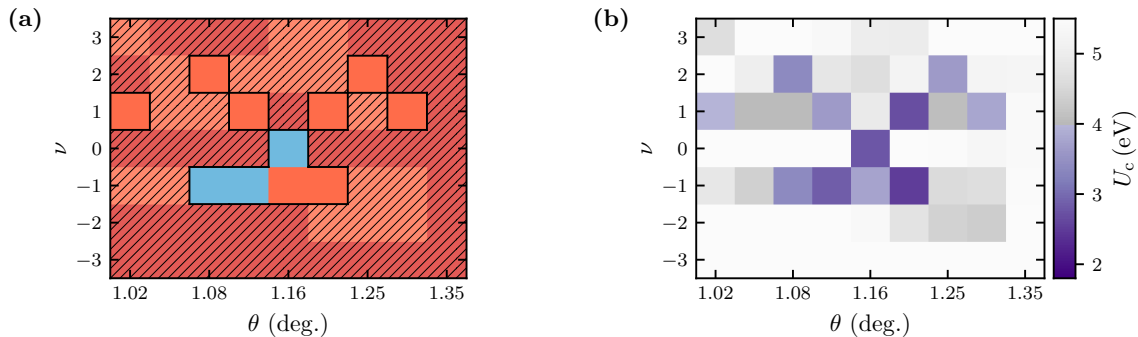

FIG. 4. (a) - Magnetic phase diagram of AtABC as a function of twist angle θ and integer doping level ν per moiré unit cell. Blue corresponds to ferromagnetic order, orange corresponds to ferrimagnetic order, and red corresponds to anti-ferromagnetic order. Regions where the critical value of the Hubbard parameter is smaller than its physical value are hatched. (b) - Critical interaction strength U_c required for the onset of magnetic instabilities in AtABC as a function of twist angle θ and integer doping levels in the flat bands ν .

with $U_c < U = 4$ eV are found for a range of doping levels and twist angles. When $U_c > U = 4$ eV, we hatch over the magnetic order to indicate that we do not expect it to occur. In Fig. 4(b) we plot the corresponding value of U_c for each $\theta - \nu$ combination and if $U_c > U = 4$ eV we use a grey scale. The FM state is only found at the magic angle at charge neutrality or at slightly smaller twist angles for $\nu = -1$ (i.e., when one hole is added per moiré unit cell). Interestingly, the character of the FM state for $\nu = -1$ slowly transitions from purely FM to a mixture of FM and FIM as a function of the twist angle.

The other broken symmetry states in the phase diagram are of FIM type and occur at $\nu = -1$ at and very close to the magic-angle, but also for the electron doped systems ($\nu = 1$ or $\nu = 2$) over a range of twist angles. In contrast, AFM order is never found in the phase diagram. While this type of order is the leading instability for a range of $\theta - \nu$ values, the corresponding critical values of the Hubbard parameter are always larger than the physical value ($U_c > U = 4$ eV) and therefore this order is not realized. This can be attributed to the fact that the AFM order is inherited from the parent ABC trilayer system which has a high value of U_c [108].

Having presented the band structure, effects of electron-electron interactions and magnetic order of AtABC, a natural question to ask is: how promising is AtABC for the observation of strong correlation phenomena in comparison to other graphitic moiré materials? Among the graphene-based moiré materials that have been studied experimentally to date, only tBLG and tTLG exhibit both correlated insulator states and robust superconductivity [13, 50]. In contrast to AtABC, the long-ranged Coulomb interaction plays an important role in these systems and enlarges the size of the region in the $\theta - \nu$ phase diagram where broken symmetry states occur [89, 105]. Based on this empirical evidence, one could argue that moiré systems that do not contain any untwisted pairs of neighboring layers [80] are more promis-

ing candidates for the observation of strongly correlated phases than moiré materials that contain untwisted layers [109]. While this might be true in the absence of electric fields, recent reports suggest that magic-angle mono-bilayer (AtAB) graphene exhibits both correlated insulating states as well as signatures of superconductivity when an electric field is applied perpendicular to the layers [44]. For comparison against AtABC, we have also calculated the phase diagram of AtAB, see Sec. IV. of the SM. Our analysis reveals that these systems exhibit qualitatively similar types of magnetic order, which suggests that AtABC may also be a promising candidate for the observation of strong correlation phenomena in the presence of applied electric fields.

To put this prediction on a stronger footing, we calculated the interacting spin susceptibility of magic-angle (1.16°) AtABC as a function of applied electric field and doping, as shown in Fig. 5. A perpendicular electric field introduces an additional onsite potential, which is approximately constant within a layer, but that varies linearly between the layer. We define Δ as the potential difference between two adjacent layers, such that the onsite potential of layer l (where $l = 1, 2, 3, 4$ with 1 corresponding to the twisted monolayer) is given by $-\Delta \cdot l$. Negative values of Δ mean that the potential energy of the electrons is lowest in the twisted monolayer. This potential difference is directly proportional to the applied electric field, with values of $|\Delta| = 30$ meV being well within experimental reach [83].

In the absence of a field, we only expect magnetic order to occur at charge neutrality or $\nu = -1$ at 1.16° [see Fig. 4(a)]. Upon applying an electric field which lowers the energy of electrons in the twisted layers ($\Delta < 0$), we find that the system is more susceptible to magnetic ordering. Overall, we find mainly FIM order in electron-doped systems, but the hole-doped systems do not generally become more susceptible to magnetic ordering, with the exception of $\nu = -1$ at $\Delta = -5$ meV

FIG. 5. (a) Magnetic phase diagram of 1.16° AtABC as a function of potential difference between adjacent layers Δ (which is proportional to a perpendicular electric field) and integer doping level ν per moiré unit cell. Blue corresponds to ferromagnetic order, orange corresponds to ferrimagnetic order, and red corresponds to anti-ferrimagnetic order. Regions where the critical value of the Hubbard parameter is smaller than its physical value are hatched. (b) Critical interaction strength U_c required for the onset of magnetic instabilities in 1.16° AtABC as a function of layer-dependent onsite potential difference Δ and integer doping levels in the flat bands ν .

[see Fig. 5(b)]. Therefore, the electron-hole asymmetry of the magnetic phase diagram becomes more pronounced in an electric field which lowers the energy of the electrons in the twisted layers relative to the other layers. On the other hand, electric fields which increase the energy of the electrons in the twisted layers ($\Delta > 0$) generally cause the system to be less susceptible to magnetic ordering. For electron-doped $\Delta > 0$ systems in a small field, we find that FIM occurs at $\nu = 1, 2$, but for larger field strengths this magnetic order disappears. In experiments on magic-angle AtAB performed by Chen *et al.* [44], there were similar trends in terms of where the correlated insulating states occur in the space of doping level and electric field. For an electric field which lowers the energy of the monolayer (relative to the AB bilayer), correlated insulating states were found at all integer electron doping levels, similar to tBLG [44]. Whereas, for an electric field which lowers the energy of the AB stacked bilayer (relative to the monolayer), a correlated insulating state was only observed at $\nu = 2$, similar to tDBLG [44]. As we have found that AtABC has a similar electronic structure and electron interactions to AtAB, this also suggests similarities in their broken symmetry phases.

In summary, we have established magic-angle AtABC as a highly promising candidate for the observation of broken symmetry phases, such as magnetic order. To test our predictions, we propose that transport experiments on magic-angle AtABC should be carried out to measure the phase diagram as function of doping. Additionally, scanning tunnelling microscopy can be used to verify the presence of an additional van Hove singularity in AtABC. These measurement techniques can also identify correlated insulating states and superconductivity. Promising future directions for theoretical work on AtABC is to study its topological properties, possible superconductivity mechanisms, and nematic ordering.

I. ATOMIC STRUCTURE

We study commensurate moiré unit cells of monolayer graphene twisted on trilayer graphene comprising of ABA or ABC stacking. The monolayer and trilayer are initially stacked directly on top of each other, and the top monolayer is rotated anticlockwise about an axis normal layers that passes through a carbon atom in the monolayer and (at least) the top layer of the trilayer. The moiré lattice vectors are $\mathbf{R}_1 = n\mathbf{a}_1 + m\mathbf{a}_2$ and $\mathbf{R}_2 = -m\mathbf{a}_1 + (n + m)\mathbf{a}_2$ [1], where n and m are integers that specify the moiré unit cell in terms of the graphene lattice vectors \mathbf{a}_1 and \mathbf{a}_2 with the lattice constant of graphene being $a_0 = 2.42 \text{ \AA}$.

In Figs. 1 and 2, we display the structure of the studied graphene twisted on trilayer graphene systems. These structures are obtained from minimising the energy of the AIREBO-morse [2] and KC [3] potential for graphene, as implemented in LAMMPS [4]. As mentioned in the main text, we find the relaxations of the graphene on trilayer graphene systems have some resemblance to twisted bilayer graphene (tBLG) and also twisted double bilayer graphene (tDBLG).

Both AtABC (graphene twisted on a ABC stacked trilayer graphene) and AtABA (graphene twisted on a ABA stacked trilayer graphene) exhibit similar lattice reconstruction, as shown in Figs. 1 and 2, with the relaxation features being analogous to tBLG and tDBLG with AB bilayers [5]. In both of these structures, the twisted graphene layer (layer 1) and the graphene layer that is in contact with the twisted layer (layer 2) undergo the most significant relaxations. These two layers form a “tBLG unit”, and the relaxation effects of these layers in AtABC and AtABA can be seen to be analogous. Namely, there are peaks in the z -displacement in the AA regions of these layers, owing to the unfavourable stacking order; and the in-plane displacements have an opposite sense in each layer, such that the AB stacking order is increased relative to AA.

In layer 3 of both structures, there are similar magnitudes of the z -displacements as layer 2. However, the in-plane displacements on layer 3 are significantly less pronounced than layers 1/2. This indicates that the ABC and ABA stacking is not perfectly retained throughout the whole moiré unit cell. In layer 4 there are similar in-plane and out-of-plane relaxations as layer 3, but the magnitudes of the displacements are even smaller.

* These authors contributed equally

FIG. 1. Out-of-plane and in-plane relaxations of AtABC for a twist angle of $\theta = 0.73^\circ$. [(a)-(d)] Out-of-plane displacements for layers 1 to 4, respectively; [(e)-(h)] In-plane displacements for layers 1 to 4, respectively.

FIG. 2. Out-of-plane and in-plane relaxations of AtABA for a twist angle of $\theta = 0.73^\circ$. [(a)-(d)] Out-of-plane displacements for layers 1 to 4, respectively; [(e)-(h)] In-plane displacements for layers 1 to 4, respectively.

II. ELECTRONIC STRUCTURE FROM TIGHT-BINDING

The electronic structure was investigated with an atomistic tight-binding model, which is a reliable method for determining the electronic structure of graphene-based moiré materials. In the atomistic tight-binding formalism, the Hamiltonian is given by

$$\hat{\mathcal{H}} = \sum_i \varepsilon_i \hat{c}_i^\dagger \hat{c}_i + \sum_{ij} [t(\mathbf{t}_i - \mathbf{t}_j) \hat{c}_j^\dagger \hat{c}_i + \text{H.c.}]. \quad (1)$$

Here \hat{c}_i^\dagger and \hat{c}_i are, respectively, the electron creation and annihilation operators associated with the p_z -orbital on atom i . The ε_i is the on-site energy of the p_z -orbitals, which is used to fix the Fermi energy at 0 eV. The hopping parameters $t(\mathbf{t}_i - \mathbf{t}_j)$ between atoms i and j (located at $\mathbf{t}_{i/j}$) are determined using the Slater-Koster rules

$$t(\mathbf{r}) = \gamma_1 \exp\{-(|\mathbf{r}| - d)/\delta_0\} \cos^2 \varphi + \gamma_0 \exp\{-(|\mathbf{r}| - a)/\delta_0\} \sin^2 \varphi. \quad (2)$$

Here $\gamma_1 = 0.48$ eV and $\gamma_0 = -2.70$ eV correspond to σ and π hopping between p_z -orbitals, respectively. The carbon-carbon bond length is $a = 1.397$ Å and the interlayer separation parameter is taken to be $d = 3.2912$ Å. The decay parameter of the hoppings is set to $\delta_0 = 0.184a_0$. The angle-dependence of hoppings are captured through φ , which is the angle corresponding between the z -axis and the vector connecting atoms i and j . Hoppings between carbon atoms whose distance is larger than the cutoff 10 Å are neglected.

In Fig. 3 we display additional band structures for AtABC, AtABA, AtAB and AtAtA as a function of twist angle. There are similarities between the AtAB and AtABC band structures, as discussed in the main text. An analogy can also be drawn between AtABA and AtAtA, from the fact that both systems have a Dirac cone intersecting the flat moiré bands.

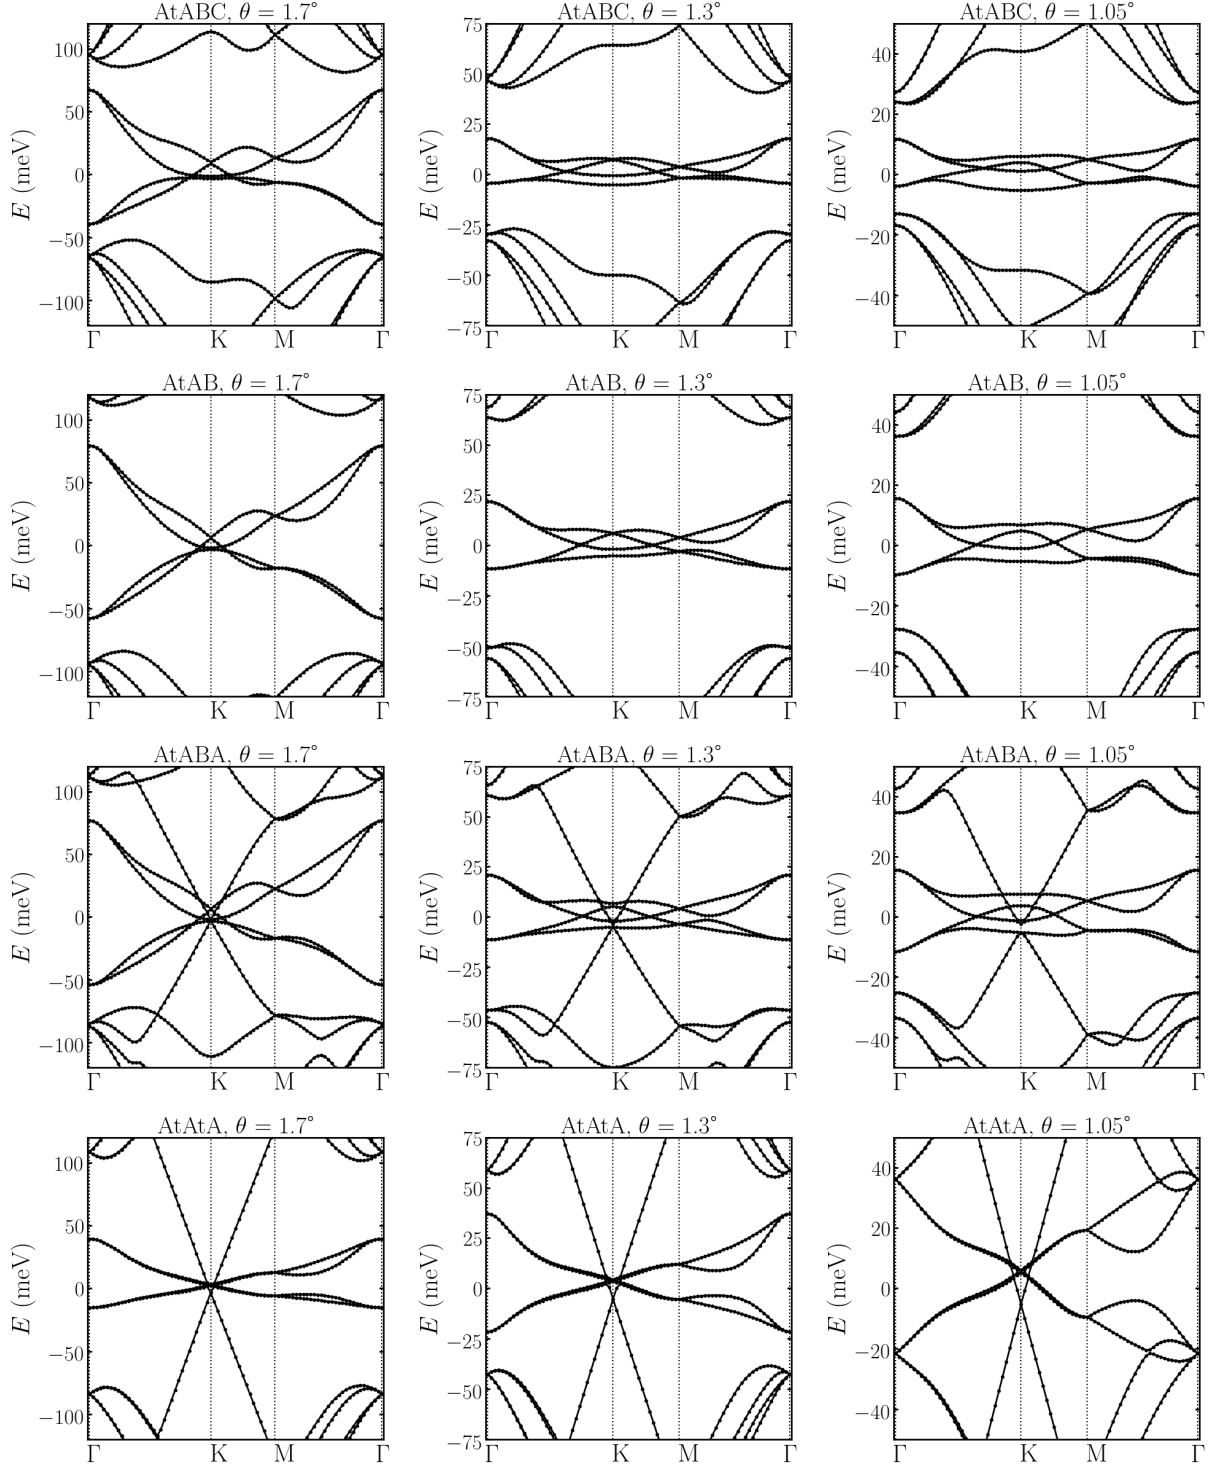

FIG. 3. Band structures from the atomistic tight-binding model along the high symmetry path. Relaxed atomic positions were used in each case.

III. HARTREE INTERACTIONS

The long-ranged electron-electron interaction contribution to the Hamiltonian can be included through

$$\varepsilon_i = \int d\mathbf{r} \phi_z^2(\mathbf{r} - \boldsymbol{\tau}_i) V_H(\mathbf{r}), \quad (3)$$

where $\phi_z(\mathbf{r})$ is the p_z orbital of the carbon atoms and $V_H(\mathbf{r})$ is the Hartree potential. The Hartree potential is determined from the electron density $n(\mathbf{r})$ and the screened electron-electron interaction $W(\mathbf{r})$, as seen by

$$V_H(\mathbf{r}) = \int d\mathbf{r}' W(\mathbf{r} - \mathbf{r}') [n(\mathbf{r}') - n_0(\mathbf{r}')], \quad (4)$$

where $n_0(\mathbf{r})$ is a reference electron density of the uniform system. The electron density is determined through

$$n(\mathbf{r}) = \sum_{n\mathbf{k}} f_{n\mathbf{k}} |\psi_{n\mathbf{k}}(\mathbf{r})|^2 \quad (5)$$

where $\psi_{n\mathbf{k}}(\mathbf{r})$ is the Bloch eigenstate of the atomistic tight-binding model, with subscripts n and \mathbf{k} denoting the band index and crystal momentum, respectively; $N_{\mathbf{k}}$ is the number of \mathbf{k} -points in the summation of the electron density, and $f_{n\mathbf{k}} = 2\Theta(\varepsilon_F - \varepsilon_{n\mathbf{k}})$ is the spin-degenerate occupancy of state $\psi_{n\mathbf{k}}$ with eigenvalue $\varepsilon_{n\mathbf{k}}$ (where ε_F is the Fermi energy). Inserting the Bloch states in Eq. (5) gives

$$n(\mathbf{r}) = \sum_j n_j \chi_j(\mathbf{r}), \quad (6)$$

where $\chi_j(\mathbf{r}) = \sum_{\mathbf{R}} \phi_z^2(\mathbf{r} - \boldsymbol{\tau}_j - \mathbf{R})$ (with \mathbf{R} denoting the moiré lattice vectors) and the total number of electrons on the j -th p_z -orbital in the unit cell being determined by $n_j = \sum_{n\mathbf{k}} f_{n\mathbf{k}} |c_{n\mathbf{k}j}|^2 / N_{\mathbf{k}}$, with $c_{n\mathbf{k}j}$ denoting the coefficients of the eigenvectors of the tight-binding model.

The reference density is taken to be that of a uniform system, $n_0(\mathbf{r}) = \bar{n} \sum_j \chi_j(\mathbf{r})$, where \bar{n} is the average of n_j over all atoms in the unit cell, which is related to the filling per moiré unit cell ν through $\bar{n} = 1 + \nu/N$, where N is the total number of atoms in a moiré unit cell [6]. This reference density is taken to prevent overcounting the intrinsic graphene Hartree contribution which should be included in the hopping parameters of Eq. (1).

In experiments, there is often a metallic gates above and below the moiré material, with a hexagonal boron nitride (hBN) substrate separating the gates from moiré materials. These

metallic gates add/remove electrons from moiré material and can also create electric fields across the system. These gates also screen the electron interactions in moiré material, and taking this effect into account has been shown to be important in tBLG [7]. Therefore, we utilise a double metallic gate screened interaction

$$W(\mathbf{r}) = \frac{e^2}{4\pi\epsilon_0\epsilon_{\text{bg}}} \sum_{m=-\infty}^{\infty} \frac{(-1)^m}{\sqrt{|\mathbf{r}|^2 + (2m\xi)^2}}, \quad (7)$$

where ξ is the thickness of the hBN dielectric substrate, with dielectric constant ϵ_{bg} , separating tDBLG from the metallic gate on each side [7–9]. We set $\xi = 10$ nm and the value of $\epsilon_{\text{bg}} = 4$ for all calculations.

In our atomistic model, we neglect contributions to the electron density from overlapping p_z -orbitals that do not belong to the same carbon atom, which is equivalent to treating $\phi_z^2(\mathbf{r})$ as a delta-function. Therefore, we calculate the Hartree on-site energies using

$$\varepsilon_i = \sum_{j\mathbf{R}} (n_j - \bar{n}) W_{\mathbf{R}ij}, \quad (8)$$

where $W_{\mathbf{R}ij} = W(\mathbf{R} + \boldsymbol{\tau}_j - \boldsymbol{\tau}_i)$. If $\mathbf{R} = 0$ and $i = j$, we set $W_{0,ii} = U/\epsilon_{\text{bg}}$ with $U = 17$ eV [10].

To obtain a self-consistent solution of the equations, we use a 8×8 k-point grid to sample the first Brillouin zone to converge the density in Eq. (5) and we sum over a 11×11 supercell of moiré unit cells to converge the on-site energy of Eq. (8). Linear mixing of the electron density is performed with a mixing parameter of 0.1 or less (i.e., the addition of 10 percent of the new potential to 90 percent of the potential from the previous iteration). Typically, the Hartree potential converges to an accuracy of better than 0.1 meV per atom within 100 iterations. For doping levels where the moiré material is metallic, smaller mixing values and more iterations are sometimes needed to reach this convergence threshold as the lack of smearing causes states very close in energy to flick between being occupied and un-occupied in consecutive iterations.

In Fig. 4 we show the quasiparticle band structure for AtAB and AtABC for a number of doping levels and twist angles. Overall, we find that the electronic structure is rather insensitive to the long-ranged electron-electron interactions. We do observe some trends, albeit with small magnitudes. Upon electron doping, we find that the Dirac cone of the flat bands increases in energy relative to the quadratic/cubic bands. This is because the Dirac cone is predominantly from the upper twisted layers, and upon filling these states electrons are put into these layers, which in turn causes the Hartree potential to increase

on these layers and shift up the energy of these states. The changes in the band structure predominately come from layer-dependent differences, rather than in-plane variations. The scale of the Hartree potential is quite small, and there is not a clean localisation of states which can give rise to significant band distortions that are observed in tBLG. Therefore, we can safely neglect the long-ranged Hartree interactions and just use the tight-binding model for magnetic calculations.

FIG. 4. Band structures from the atomistic tight-binding model along the high symmetry path with Hartree interactions at integer doping levels per moiré unit cell.

IV. MAGNETIC STRUCTURE

This section shows the Random Phase Approximation (RPA) used to analyze the magnetic ordering tendencies of both AtABC and AtAB graphene (which are presented here).

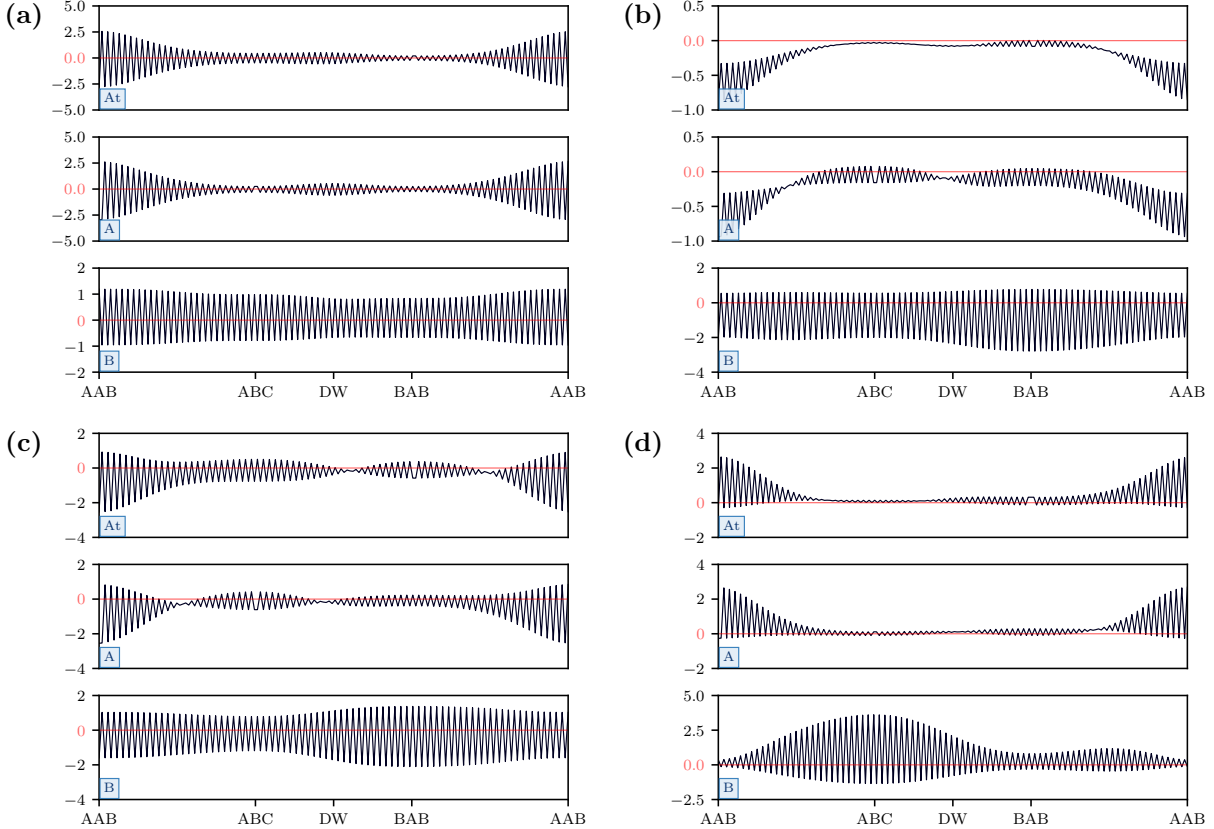

FIG. 5. Linecut of different magnetic ordering through the long diagonal of the moiré unit cell for the three layers of AtAB graphene at various angles and fillings. The local stacking sequence is shown at the bottom of each panel, where DW stands for the domain wall region of the moiré pattern. **(a)**: $\theta = 1.20^\circ, \nu = 2$ – ordering tendency that is strongly anti-ferromagnetic in each layer with more pronounced localization in the twisted two layers. **(b)**: $\theta = 1.20^\circ, \nu = -3$ – ordering tendency that is mainly ferromagnetic in the twisted layers with reminiscent anti-ferromagnetic order, with ferrimagnetic order in the lower layer. **(c)**: $\theta = 1.25^\circ, \nu = 3$ – ordering where there is modulated ferrimagnetic order in the layers with a relative twist angle, and uniform anti-ferromagnetic order in the lower untwisted layer. **(d)**: $\theta = 1.16^\circ, \nu = 1$ – order that has strongly modulated ferrimagnetic order in all layers.

FIG. 6. Magnetic phase diagram of AtAB graphene for twist angles (θ) around the first magic angle and integer fillings (ν , where negative values are hole doped, 0 is charge neutrality and positive values are electron doped). **(a)**: Types of magnetic order: Blue corresponds to ferromagnetic order, orange corresponds to ferrimagnetic order, and red corresponds to anti-ferromagnetic order. We have hatched out the where the values of U_c are lower than 4 eV. **(b)**: Critical interaction strength U_c required for the onset of magnetic instabilities.

A. Random Phase Approximation

Following Refs. 11 and 12 to analyze the magnetic ordering tendencies of graphitic moiré systems, we calculate the spin susceptibility $\chi_{ij}(\mathbf{q}, q_0)$ in its long-wavelength, static limit $\mathbf{q} = q_0 = 0$:

$$\hat{\chi} = \hat{\chi}(\mathbf{q} = 0, q_0 = 0) = \frac{T}{N_{\mathbf{k}}} \sum_{\mathbf{k}, k_0} \hat{G}(\mathbf{k}, k_0) \circ \hat{G}^T(\mathbf{k}, k_0). \quad (9)$$

The Matsubara Green's function reads $\hat{G}(\mathbf{k}, k_0) = (ik_0 - \hat{H}(\mathbf{k}))^{-1}$ with the non-interacting part of the Hamiltonian $\hat{H}(\mathbf{k})$. Since we approximate the interacting part of the Hamiltonian by a local Hubbard interaction, the renormalized interaction reads

$$\hat{W} = \frac{U^2 \hat{\chi}}{\mathbb{1} + U \hat{\chi}}. \quad (10)$$

Employing Stoner's criterion, we find an ordered state if the smallest eigenvalue χ^0 of the matrix $\hat{\chi}$ reaches $-1/U$, or, vice versa, we can investigate the critical interaction strength $U_c = -1/\chi^0$ below which the system will go into an ordered state. The eigenvector corresponding to the eigenvalue χ^0 is proportional to the system's magnetization in its ordered state. The numerical evaluation procedure is identical to the one presented in Ref. 12 – we use $N_{k_0} = 500$ Matsubara frequencies and $N_{\mathbf{k}} = 24$ momentum points at a temperature of $T = 10^{-4}$ eV.

B. Results for AtAB

Similarly to the AtABC system, the magnetic orderings found in AtAB graphene can be classified as modulated AFM order [Fig. 5 (a)], modulated FM in the top two layers and FIM in the bottom layer [Fig. 5 (b)] and two types of FIM order [Fig. 5 (c), (d)]. Compared to AtABC graphene, the U_c is low mostly at $\nu = 0$ and $\nu = -3$ [Fig. 6 (b)] with FM orders being more prominent in the magnetic phase diagram [Fig. 6 (a)].
