Decoherence-free subspaces allow for the preparation of coherent and entangled qubits for quantum computing. Decoherence can be dramatically reduced, yet dissipation is an integral part of the scheme in generating stable qubits and manipulating them via one- and two-bit gate operations. How this works can be understood by comparing the system with a three-level atom exhibiting a macroscopic dark period. In addition, a dynamical explanation is given for a scheme based on atoms inside an optical cavity in the strong-coupling regime and we show how spontaneous emission by the atoms can be highly suppressed.

I. INTRODUCTION

A major development in recent decades was the realization that computation is a purely physical process [1]. What operations are computationally possible and with what efficiency depends upon the physical system employed to perform the calculation. The field of quantum computing has developed as a consequence of this idea, using quantum systems to store and manipulate information. It has been shown that such computers can enable an exponential speed up in the time taken to compute solutions to certain problems over that taken by a purely classical device [2–4].

To obtain a quantum-mechanical bit (qubit), two well-defined, orthogonal states, denoted by |0⟩ and |1⟩, are needed. There are certain minimum requirements for any realization of a universal quantum computer [5]. It must be possible to generate any arbitrary entangled superposition of the qubits. As shown by Barenco et al. [6], to achieve this, it suffices to be able to perform a set of universal quantum logic gates. The set considered in this paper consists of the single-qubit rotation and the controlled-NOT gate between two qubits. In addition, the system should be scalable with well characterized qubits and it has to be possible to read out the result of a computation. Finally, the error rates of the individual gate operations should be less than 10⁻⁴ to assure that the quantum computer works fault tolerant[7].

To achieve the required precision, the relevant decoherence times of the system have to be much longer than that of a single gate operation and it is this that constitutes the main obstacle for quantum computing to overcome. To avoid decoherence it has been proposed that decoherence-free (DF) states should be used as qubits. The existence of decoherence-free subspaces (DFSs) has been discussed widely in the literature by several authors (see [8–12] and references therein). These subspaces arise if a system possesses states that do not interact with the environment. In addition, the system’s own time evolution must not drive the states out of the DFS. Recently, the existence of DFSs for photon states has been verified experimentally by Kwiat et al. [13] and for the states of trapped ions by Kielpinski et al. [14].

Far less is known about the manipulation of a system inside a DFS. One way is to use a Hamiltonian that does not excite transitions out of the DFS, as has been discussed by Bacon et al. [15]. Alternatively, one can make use of environment-induced measurements [16] and the quantum Zeno effect [17–19] as proposed by Beige et al. [12,20] (see also [21]). The quantum Zeno effect predicts that any arbitrary but sufficiently weak interaction does not move the state of a system out of the DFS, if all non-DF states of the system couple strongly to the environment and populating them leads to an immediate photon emission. The system then behaves as if it were under continuous observation as to whether it is in a DF state or not. Initially in a DF state, the system remains DF with a probability very close to unity. This idea leads to a realm of new possibilities to manipulate DF qubits.

The possibility of quantum computing using dissipation has been pointed out already by Zurek in 1984 [22] but so far no concrete example for a scheme based on this idea has been found. In this paper we discuss in detail such a proposal for quantum computing by Beige et al. outlined in [20] and simplify its setup. Advantages of this scheme are that it allows for the presence of finite decay rates and that its implementation is relatively simple, which should make its experimental realization much less demanding. The precision of gate operations is independent of most system parameters and the decoherence times are much longer than the duration of gate operations.

In the last few years, many proposals for the implementation of quantum computing have been made taking advantage of advances in atom- and ion-trapping technology. Such methods mainly differ in the nature of the coupling between the qubits, e.g., using collective vibrational modes [24–27], a strongly coupled single-cavity mode [28–31] or the dipole-dipole interaction between atoms [32–34]. The physical system considered here consists of N atoms (or ions) stored in a linear trap [35], inside an optical lattice [36], or on top of an atomic chip for quantum computing [37–39] and interacting via a common-cavity radiation-field mode. Each qubit is, as in [40], obtained from two ground states of an atom, which we call state 0 and 1. The number of qubits is thus the same as the number of atoms and the system is scalable.

*Present address: Max-Planck-Institut für Quantenoptik, Hans-Kopfmann-Straße 1, 85748 Garching, Germany.
For simplicity we assume here that the coupling strength for by Raman transitions is small. More realistically, one can replace all the transitions success rate if the spontaneous decay rate of the upper level we discuss in the beginning of this paper involves three-level come populated during a gate operation. The simple scheme spontaneous emission from excited atomic states, which only be-

The single-qubit rotations can easily be achieved independently of the cavity by using the well-known method of adiabatic population transfer via an excited state [41,42]. Another crucial component of any quantum computer is a mechanism for measuring the qubits in the computational basis. For this a proposal by Dehmelt [23] can be used. An additional rapidly decaying level is strongly coupled to one of the ground states with a short laser pulse. The presence or absence of scattered photons then gives an accurate measurement of the atomic state. Further details and extensions of this method are given in [43,44].

To perform a controlled-\textit{NOT} gate, the two atoms involved have to be moved into a cavity as shown in Fig. 1 and maintained a suitable distance apart to enable laser pulses to address each atom individually. The coupling constant of each atom to the cavity mode is denoted in the following by \( g^{(i)} \). For simplicity we assume here that the coupling strength for both atoms is the same and \( g^{(1)}=g^{(2)}=g \). To couple non-neighboring atoms, ring cavities with a suitable geometry could be used.

The main source of decoherence in cavity schemes is the possibility of a photon leaking out of the cavity through imperfect mirrors with a rate \( \kappa \). Here the qubits are obtained from atomic ground states, and so the system is protected against this form of decoherence while no gate is performed. Additionally the two atoms in the cavity possess a further DF state involving excited atomic levels and an empty cavity. This state is a maximally entangled state of the atoms and populating it allows the entanglement in the system to change and the controlled-\textit{NOT} gate operation to be realized without populating the cavity mode. To prevent the population of non-DF states, we use the idea described above for the manipulation of a DFS, which is explained in terms of adiabatic manipulation of DF states.

The second source of decoherence in the scheme is spontaneous emission from excited atomic states, which only become populated during a gate operation. The simple scheme we discuss in the beginning of this paper involves three-level atoms with a \( \Lambda \) configuration. It only works with a high success rate if the spontaneous decay rate of the upper level is small. More realistically, one can replace all the transitions by Raman transitions [41,42] by using three additional levels per atom. We show that the resulting six-level atoms behave like the \( \Lambda \) systems discussed before but with a highly reduced probability for a spontaneous photon emission. As an example we consider \( ^{40}\text{Ca}^+ \) ions as in the experiment by Guthörlein \textit{et al}. [35].

The paper is organized as follows. In Sec. II we give a detailed discussion of the realization of the controlled-\textit{NOT} gate using three-level atoms and show that the behavior of our scheme has close parallels with the well-known behavior of a single three-level atom exhibiting macroscopic dark periods [23]. As will be shown in this paper, moving to the correct parameter regime enables the operation to be completed with a high success rate and high fidelity of the output. The use of further levels to reduce the decoherence from spontaneous emission is covered in Sec. III. Finally, Sec. IV offers a summary of our results.

\section{II. The realization of the controlled-\textit{NOT} gate with a single laser pulse}

To perform a controlled-\textit{NOT} gate, one has to realize a unitary operation between the two qubits involved. This transformation flips the value of the target qubit conditional on the control qubit being in state \( |1\rangle \). Writing the state of the two qubits as a control state followed by a target state, the corresponding unitary operator equals

\begin{equation}
U_{\text{CNOT}}=|00\rangle\langle 00|+|01\rangle\langle 01|+|10\rangle\langle 11|+|11\rangle\langle 10|.
\end{equation}

In this section we discuss a possible realization of this gate. First an intuitive explanation is given, followed by an analytic derivation of the time evolution of the system. The success rate of a single gate operation and its fidelity under the condition of no photon emission are calculated.

To realize a controlled-\textit{NOT} gate between two qubits the corresponding two atoms are placed at fixed positions inside a cavity as shown in Fig. 1. To obtain a coupling between the atoms via the cavity mode, an additional level, level 2, is used. We assume in the following, that the qubit states \( |0\rangle \) and \( |1\rangle \) together with \( |2\rangle \) form a \( \Lambda \) configuration as shown in Fig. 2. The 1-2 transition of each \( \Lambda \) system couples with the strength \( g \) to the cavity mode, while the 0-2 transition is strongly detuned. In addition two laser fields are required. One laser couples with the Rabi frequency \( \Omega_1 \) to the 1-2 transition of atom 1, the other couples with \( \Omega_0 \) to the 0-2 transition of atom 2 and we choose

\begin{equation}
\Omega_0=\Omega_1=\sqrt{2}\Omega.
\end{equation}
Note that this choice of the Rabi frequencies is different from the choice in [20]. There we minimized the error rate, whereas here we are interested in improving the feasibility of the proposed scheme by simplifying its setup. Only one laser is actually required per atom.

As in [20] we assume in the following that the Rabi frequency $\Omega$ is weak compared to the coupling constant $g$ and the decay rate $\kappa$. On the other hand, $\Omega$ should not be too small because otherwise spontaneous emission from level 2 during the gate operation cannot be neglected. This leads to the condition

$$\Gamma \ll \Omega \ll \frac{g^2}{\kappa} \quad \text{and} \quad \kappa. \quad (3)$$

It is shown in the following that under this condition a laser pulse of duration

$$T = \sqrt{2} \pi \frac{\Omega}{\kappa} \quad (4)$$

transforms the initial state of the atoms by a controlled-NOT operation.

In this section we consider only the two atoms inside the cavity, the laser, the cavity field, and the surrounding free-radiation fields. In the following we denote the energy of level $x$ by $\hbar \omega_x$, the energy of a photon with wave number $k$ by $\hbar \omega_k$, and $\omega_{\text{cav}}$ is the frequency of the cavity field with

$$\omega_{\text{cav}} = \omega_2 - \omega_1. \quad (5)$$

The annihilation operator for a photon in the cavity mode is

$$a_{\text{cav}} = \sum_{x} \sqrt{2} \hbar \omega_x |x\rangle \langle x|, \quad \kappa \quad \text{and} \quad \kappa. \quad (6)$$

where

$$H_{\text{cav}} = H_{\text{at-cav}} + H_{\text{cav-env}} + H_{\text{at-env}} + H_{\text{laser}}.$$

The annihilation operator for a photon in the cavity mode is given by $b$, and for a photon of the free-radiation field of the mode $(k,\lambda)$, by $a_{k\lambda}$ or $\tilde{a}_{k\lambda}$, for those coupled to the atom or cavity, respectively. (The geometry of the setup requires separate fields for each.) The coupling of the $j-2$ transition of atom $i$ to the free-radiation field can be described by coupling constant $g^{(j)}_{ik}$, while $\tilde{g}_{k\lambda}$ characterizes the coupling of the cavity mode to a different free-radiation field. Using this notation, the interaction Hamiltonian of the system with respect to the free Hamiltonian can be written as

$$H_{\text{inter}} = \sum_i \left[ 2 | \tilde{a} \rangle \langle a | + | a \rangle \langle a | - \hbar | H. C. \right]. \quad (7)$$

Note that this choice of the Rabi frequencies is different from the choice in [20]. There we minimized the error rate, whereas here we are interested in improving the feasibility of the proposed scheme by simplifying its setup. Only one laser is actually required per atom.

[FIG. 3. Analogy between two systems with a macroscopic dark period. (a) Level scheme of a three-level atom with dark state $|A\rangle$. Here $\Omega_s$ is the Rabi frequency of the strong laser driving the $B-C$ transition, $\Omega_{w}$ is the Rabi frequency of the weak laser driving the $A-B$ transition, and $\Gamma_s$ is the decay rate of level $C$. (b) Schematic view of the level scheme of the two atoms inside the cavity. The dark state $|A\rangle$ is replaced by the DFS, $|B\rangle$ by the subspace of the non-DF states with no photons in the cavity ($n=0$), and $|C\rangle$ by a subspace containing non-DF states with the cavity mode populated ($n>0$). The analog to $\Omega_w$ is $\Omega_s$, the analog of $\Omega_s$ is $g$, and $\Gamma_s$ is replaced by $\kappa$.]

These terms describe the interaction of the atoms with the cavity mode and the coupling of the cavity or the atoms, respectively, to the external fields and the effect of the laser on the atomic state.

**A. Quantum computing in a dark period**

In this section we provide a simple description of the physical mechanism underlying our proposal. To do so we point out that there is a close analogy between this scheme and the single three-level atom shown in Fig. 3(a). The atom has a metastable level $A$, which is weakly coupled via a driving laser with Rabi frequency $\Omega_s$ to level $B$. Level $B$ in turn is strongly coupled to a rapidly decaying third level $C$. We denote the Rabi frequency of this driving $\Omega_s$, the decay rate of the upper level $\Gamma_s$, and assume in the following that

$$\Omega_w \ll \frac{\Omega_s^2}{\Gamma_s} \quad \text{and} \quad \Gamma_s. \quad (8)$$

Let us assume that the atom is initially in the metastable state $|A\rangle$. In the absence of the strong driving ($\Omega_s=0$) the atom goes over into the state $|B\rangle$ within a time $\pi/\Omega_w$. If the strong laser pulse is applied, the atoms remain in $|A\rangle$ much longer on average, namely, about the mean time before the first photon emission from level $C$, which equals [45]

$$T_{\text{dark}} = \frac{\Omega_s^2}{\Omega_w \Gamma_s} \gg \frac{\pi}{\Omega_w}. \quad (9)$$

The transition from level $A$ to level $B$ is strongly inhibited, an effect known in the literature as “electron shelving” [23]. It is also known as a macroscopic dark period and state $|A\rangle$ is known as a dark state [45].

In the scheme we discuss in this paper, the levels $A$, $B$, and $C$ are replaced by subspaces of states. To show this let us first consider which states play the role of the dark state $A$. There are two conditions for dark states or decoherence-free (DF) states of a system [8–12]. First, the state of the system

032305-3
must be decoupled from the environment. Let us in the following neglect spontaneous emission by the atoms inside the cavity by setting $\Gamma = 0$. Then, this is the case for all states with $n = 0$ photons inside the cavity. Second, the atomic state must be unable to excite the cavity, requiring that $H_{\text{int,cav}}$ must annihilate it. The dark states of the system are therefore of the form $\ket{\psi} = \ket{0}_{\text{cav}} \otimes \ket{\varphi}$, where $\ket{\varphi}$ can be an arbitrary superposition of the five atomic states $\ket{00}$, $\ket{01}$, $\ket{10}$, $\ket{11}$ and the antisymmetric state $\ket{a} = \ket{\overline{12}} - \ket{21}/\sqrt{2}$. \hfill (10)

Here $\ket{n}_{\text{cav}}$ denotes the state with $n$ photons inside the cavity. The DFS of the two atoms inside the cavity is thus the span of the individual dark states shown above, resulting in a five-dimensional DFS.

The analog to the shelving system’s level $B$ is a non-DF state with no photon inside the cavity. They are coupled to the DFS via the weak driving laser with Rabi frequency $\Omega$. The analog to level $C$ are non-DF states with at least one photon in the cavity field. They become excited via coupling of the atoms to the cavity mode, with the coupling constant $g$. A photon leaks out of the cavity with a rate $\kappa$, which has the same effect as the decay rate $\Gamma_1$ above.

Using this analogy, which is summarized in Fig. 3, and replacing condition (8) by condition (3) we can now easily predict the time evolution of the two atoms inside the cavity. It suggests that the weak laser pulse does not move the state of the atoms out of the DFS. Nevertheless, the time evolution inside the DFS is not inhibited and is now governed by the effective Hamiltonian $H_{\text{eff}}$. This Hamiltonian is the projection of the laser Hamiltonian $H_{\text{laser}}(t)$ with the projector $\Pi_{\text{DFS}}$ onto the DFS and equals $H_{\text{eff}} = \Pi_{\text{DFS}} H_{\text{laser}}(t) \Pi_{\text{DFS}}$. \hfill (11)

For the choice of Rabi frequencies made here this leads to the effective Hamiltonian

$$H_{\text{eff}} = \frac{i}{2} \hbar \Omega \left[ \ket{10}\bra{a} - \ket{a}\bra{11} + \text{H.c.} \right] \otimes \ket{0}_{\text{cav}} \bra{0}.$$ \hfill (12)

If the lasers are applied for a duration $T$ as in Eq. (4), then the resulting evolution is exactly that desired, the controlled-NOT gate operation.

The length of the gate operation is chosen such that the additional DF state $\ket{a}$ is no longer populated at the end of the gate operation. It acts as a bus for the population transfer between the qubit states. By populating $\ket{a}$ one can create entanglement between the two atoms by applying only a laser field. Note, that the cavity always remains empty during the gate operation, nevertheless, it establishes a coupling between the qubits.

### B. The no-photon time evolution

In this section it is shown that the effect of the weak laser fields indeed resembles a controlled-NOT operation. We also show that the mean time before the first photon emission is of the order of $g^2/(\kappa \Omega^2)$ as suggested by Eq. (9), and the equivalence of the two schemes shown in Fig. 3. To do this we use the quantum-jump approach [46–49]. It predicts that the state $\ket{\psi(0)}$ of the two atoms inside the cavity and the cavity field under the condition of no photon emission in the $(0,t)$ is governed by the Schrödinger equation

$$i \hbar \frac{d\psi(t)}{dt} = H_{\text{cond}} \psi(t) \hfill (13)$$

with the conditional Hamiltonian $H_{\text{cond}}$. This Hamiltonian is non-Hermitian and the norm of the state vector $\ket{\psi(0)}$ is decreasing in time. From this decrease one can calculate the probability for no photon in the time period $(0,t)$, which is given by

$$P_0(t,\psi) = \| U_{\text{cond}}(t,0) \psi \|^2.$$ \hfill (14)

Here we solve Eq. (13) for the laser pulse of Eq. (2) and the parameter regime (3) with the help of an adiabatic elimination of the fast varying parameters.

If a photon is emitted, either by atomic spontaneous emission or by cavity decay, then the atomic coherence is lost, the gate operation has failed and the computation has to be repeated. The probability for no photon emission during a single gate operation, $P_0(T,\psi)$, therefore equals the success rate of the scheme. In order to evaluate the quality of a gate operation we define the fidelity $F$ of a single gate operation of length $T$ as

$$F(T,\psi) = \frac{\| (\psi|U_{\text{CNOT}} U_{\text{cond}}(T,0) \psi) \|^2}{P_0(T,\psi)}.$$ \hfill (15)

This is the fidelity of the scheme under the condition of no photon emission. If no photon detectors are used to discover whether the operation has succeeded or not, the fidelity reduces to just the numerator.

The conditional Hamiltonian for the atoms in the cavity can be derived from the Hamiltonian $H_1$ of Eq. (7) using second-order perturbation theory and the assumption of environment-induced measurements on the free-radiation field [16]. This leads to [50]

$$H_{\text{cond}} = i \hbar g \sum_i \left[ \ket{1}\bra{1} b - \text{H.c.} \right] + \frac{1}{2} \sqrt{2} \hbar \Omega (\ket{0}\bra{1} + \ket{1}\bra{0}) + i \frac{\hbar \kappa}{2} b - \frac{\hbar \Gamma}{2} \sum_i \ket{2}\bra{2}. \hfill (16)$$

The notation we adopt in describing the states of the system is as follows, $\ket{n\chi}$ denotes a state with $n$ photons in the cavity whilst the state of the two atoms is given by $\ket{x}$. Analogously to Eq. (16) we define

$$\ket{s} = \ket{\overline{12}} + \ket{21}/\sqrt{2}.$$ \hfill (17)

Writing the state of the system under the condition of no photon emission as

$$\ket{\psi(0)} = \sum_{n,\chi} c_{n\chi} \ket{n\chi}, \hfill (18)$$

one finds
\[
\begin{align*}
\dot{c}_{n00} &= -\frac{i}{2} \sqrt{2} \Omega c_{n20} - \frac{1}{2} n \kappa c_{n00}, \\
\dot{c}_{n01} &= -\frac{1}{2} n g c_{n-102} - \frac{1}{2} n \kappa c_{n01}, \\
\dot{c}_{n10} &= -\sqrt{2} n g c_{n-120} - \frac{i}{2} \Omega [\sqrt{2} c_{n20} + c_{na} + c_{n1}] - \frac{1}{2} n \kappa c_{n10}, \\
\dot{c}_{n11} &= -\sqrt{2} n g c_{n-12} - \frac{i}{2} \Omega [c_{ns} - c_{na}] - \frac{1}{2} n \kappa c_{n11}, \\
\dot{c}_{n02} &= \sqrt{n + 1} g c_{n+10}^{\dagger} - \frac{i}{2} \sqrt{2} \Omega c_{n00}, \\
&\quad - \frac{1}{2} (n \kappa + \Gamma) c_{n02}, \\
\dot{c}_{n20} &= \sqrt{n + 1} g c_{n+10} - \frac{i}{2} \sqrt{2} \Omega [c_{n10} + c_{n22}], \\
&\quad - \frac{1}{2} (n \kappa + \Gamma) c_{n20}, \\
\dot{c}_{na} &= -\frac{i}{2} \Omega (c_{n10} - c_{n11} + c_{n22}) - \frac{1}{2} (n \kappa + \Gamma) c_{na}, \\
\dot{c}_{ns} &= \sqrt{2(n + 1)} g c_{n+111} - \sqrt{2} n g c_{n-122} - \frac{i}{2} \Omega [c_{n10} + c_{n11} \\
&\quad + c_{n22}] - \frac{1}{2} (n \kappa + \Gamma) c_{ns}, \\
\dot{c}_{n22} &= \sqrt{2(n + 1)} g c_{n+11} - \frac{i}{2} \Omega [\sqrt{2} c_{n20} + c_{na} + c_{n22}], \\
&\quad - \frac{1}{2} (n \kappa + 2 \Gamma) c_{n22}.
\end{align*}
\]

There are two different time scales in the time evolution of these coefficients, one proportional to \(1/\Omega\) and \(1/\Gamma\) and a much shorter one proportional to \(\kappa/g^2\) and \(1/\kappa\). The only coefficients that change slowly in time are the amplitudes of the DF states. All other coefficients change much faster and adapt immediately to the system. By setting their derivatives equal to zero we can generate a closed system of differential equations for the coefficients of the DF states. Neglecting all terms much smaller than \(\Omega \kappa/g^2\), \(\kappa/\Omega\), and \(\Gamma/\Omega\) one finds

\[
\begin{pmatrix}
\dot{c}_{010} \\
\dot{c}_{011} \\
\dot{c}_{0a}
\end{pmatrix} = -\frac{1}{2} \begin{pmatrix}
10 k_1 & 2 k_1 & i \Omega \\
2 k_1 & 2 k_1 & -i \Omega \\
i \Omega & -i \Omega & 2 k_2
\end{pmatrix}
\begin{pmatrix}
c_{010} \\
c_{011} \\
c_{0a}
\end{pmatrix}
\tag{20}
\]

and

\[
\dot{c}_{000} = -4 k_1 c_{000}, \quad \dot{c}_{001} = 0
\tag{21}
\]

with

\[
k_1 = \frac{\Omega^2 \kappa}{16 g^2}, \quad k_2 = \frac{\Omega^2 \kappa}{16 g^2} + \frac{\Omega^2}{2 \kappa} + \frac{\Gamma}{2}.
\tag{22}
\]

As a consequence of condition (3) and Eq. (4) we have \(k/T \ll 1\). Therefore, solving the differential equations (20) and (21) in first order in \(k_1\) and \(k_2\) allows one to describe the effect of the laser pulse of length \(T\) already to a very good approximation.

By doing so one finds that there is a small population in level \(a\) at time \(T\). This might lead to the spontaneous emission of a photon via atomic decay at which point the controlled-NOT operation has failed. With a much higher probability, the no-photon time evolution causes the population of state \(\ket{0a}\) to vanish within a time \(t_a\) of the order of \(1/T\). Taking this into account and assuming that at the begin of the gate operation only qubit states are populated, we find

\[
U_{\text{cond}}(T + t_a, 0) = U_{\text{CNOT}}
\]

\[
-\frac{1}{4} (6 k_1 - k_2) T \ket{10} \bra{10} + \ket{11} \bra{11}
-\frac{1}{4} (10 k_1 + k_2) T \ket{11} \bra{11} + \ket{10} \bra{10}
-4 k_1 T \ket{00} \bra{00}.
\tag{23}
\]

If one neglects all terms of the order \(k/T\), then one finds that the no-photon time evolution of the system is indeed a controlled-NOT operation. In contrast to the preceding section, this has now been derived by solving the time evolution of the system analytically.

From Eq. (14) and (23) we find that the success rate of the scheme \(P_0(T, \psi)\) equals in first order

\[
P_0(T, \psi) = 1 - \frac{1}{2} (10 k_1 + k_2) T [|c_{010}|^2 + |c_{011}|^2]
\]

\[
-\frac{1}{2} (6 k_1 - k_2) T [c_{010}^* c_{010} + c_{010}^* c_{011}]
-8 k_1 T |c_{000}|^2.
\tag{24}
\]

which is close to unity and becomes arbitrarily close to unity as \(\Omega\) and \(\Gamma\) go to zero. In this case the performance of the gate becomes very slow. Nevertheless, this is successful because whilst the gate duration increases as \(1/\Omega\), Eq. (24) shows that the mean time for emission of a photon through the cavity walls scales as \(1/k_1\) and \(1/k_2\), which increases as \(1/\Omega^2\).

A main advantage of the scheme we propose here is, that if it works, then the fidelity of the gate operation does not differ from unity in the first order of \(k/T\). From Eqs. (15) and (23) we find within the approximations made above
The duration no-photon probability decreases sharply. The reason is that discussed in the following section.

method to prevent spontaneous emission by the atoms is discontinued. We shall therefore use this state as the least negligible. We shall therefore use this state as the initial state to which we apply the gate operation. For the gate operation is maximal and spontaneous emission by the atoms is in good agreement with Eq. ~5~.

It should therefore be possible that with our scheme the precision of $10^{-4}$ can be reached, which is required for quantum computing to work fault tolerantly [7].

C. Numerical results

In this section we present results obtained from a numerical integration of the differential equations (19). Figure 4 shows the success rate $P_s(T, \psi)$ for the initial qubit state $|10\rangle$ of the bus state $|0\rangle$ during the gate operation. For $\Gamma \ll \Omega_0$, for which $P_s(T, \psi)$ has been derived analytically, a very good agreement with Eq. (24) is found. If the spontaneous decay rate $\Gamma$ becomes of the order of $\Omega_0$ then the no-photon probability decreases sharply. The reason is that the duration $T$ of a single controlled-NOT gate is of the order of $1/\Omega_0$ and then also of the order of the lifetime $1/\Gamma$ of the bus state $|0\rangle$.

The fidelity of the gate operation under the condition of no photon emission through either decay channel is shown in Fig. 5. For $\Gamma = 0$ and for the chosen parameters the fidelity $F$ is in good agreement with Eq. (25). Like the success rate, it only differs significantly from unity if the spontaneous decay rate $\Gamma$ becomes of the same order of magnitude as $\Omega_0$. A method to prevent spontaneous emission by the atoms is discussed in the following section.

III. SUPPRESSING SPONTANEOUS EMISSION

The main limiting factor in the scheme discussed in the preceding section is spontaneous emission from level 2. However, we show now how this can be overcome by replacing all transitions in Fig. 2 by Raman transitions. To be able to do so three additional levels per atom are required, which we denote in the following by $e_j$. The states $|0\rangle$, $|1\rangle$, and $|2\rangle$ in the new scheme are ground states. They could be obtained, for instance, from the $^2S_{1/2}$ and $^2D_{3/2}$ levels of a trapped calcium ion as used in Fig. 6.

The new scheme now requires three strong laser fields applied to both atoms simultaneously, each exciting a $j\leftrightarrow e_j$ transition. Their function is to establish an indirect coupling between the states $|0\rangle$ and $|1\rangle$ with the state $|2\rangle$ and to generate phase factors. As before, the realization of a controlled-NOT operation requires one transition per atom to be individually addressed. One weak laser has to couple only to the $2\leftrightarrow e_1$ transition in atom 1, and another weak one only to the $2\leftrightarrow e_0$ transition in atom 2. In the following we denote the Rabi frequency of the laser with respect to the $i\leftrightarrow e_i$ transition by $\Omega_{ij}$, the corresponding detuning of the laser by $\Delta_j$ and the spontaneous decay rate of $|e_j\rangle$ is $\Gamma_j$.

The coupling of both atoms is again realized via the cavity mode, which couples to the $1\leftrightarrow e_2$ transition of each atom. The frequency of the cavity mode should equal

\[
F(T, \psi) = 1. \tag{25}
\]

FIG. 4. Success rate of a single gate operation, $P_s(T, \psi)$, as a function of the Rabi frequency $\Omega_0$ for the initial qubit state $|\psi\rangle = |10\rangle$ and for the spontaneous decay rates $\kappa = g$, $\Gamma = 0$ (a), $\Gamma' = 0.001g$ (b), and $\Gamma = 0.001g$ (c).

FIG. 5. The fidelity of a single controlled-NOT gate in case of no photon emission as a function of the Rabi frequency $\Omega_0$ for the same parameters as in Fig. 4.

FIG. 6. Level configuration of one of two calcium ions (atom 1) inside the cavity. Two of the split $^2D_{3/2}$ levels provide the states 0 and 1 to form one qubit, while level 2 (a $^2S_{1/2}$ state) provides the coupling of the atoms via the cavity field. The transition between these ground states is realized by Raman transitions via the excited states $|e_j\rangle$. The $1\leftrightarrow e_2$ transition couples to the cavity field with a coupling constant $g$ and $\Omega_{ij}$ denotes the Rabi frequency of a laser driving the $i\leftrightarrow e_i$ transition. The configuration of the second atom is similar to the first but with the polarization of the $\Omega_{21}$ laser reversed so that it now couples states $|2\rangle$ and $|e_0\rangle$, we call this Rabi frequency $\Omega_{20}$. 

$\begin{array}{c}
\text{2P}_{3/2} \\
\text{2P}_{1/2} \\
\text{2D}_{3/2} \\
\text{2D}_{3/2} \\
\text{2S}_{1/2} \\
\text{2S}_{1/2} \\
\text{m}_j = 1/2 \\
\text{m}_j = m_j + 1/2 \\
\text{m}_j = m_j + 1/2 \\
\text{m}_j = m_j + 1/2
\end{array}$
\[ \omega_{\text{cav}} = \omega_{c_2} - \omega_1 - \Delta_2 \] (26)

such that its detuning is the same as the detuning of the laser driving the 2-\(e_2\) transition. If desired, the interaction between an atom and the cavity can now be effectively switched on or off as required by switching on or off the laser, which excites the 2-\(e_2\) transition, relaxing the condition that only the two atoms involved in the controlled-NOT operation can be within the cavity. The coupling constant between each atom and the cavity mode is again denoted by \(g\) and the spontaneous decay rate of a single photon inside the cavity by \(\kappa\). Using this notation in the interaction picture with respect to the free Hamiltonian

\[ H_0 = \sum_{i=1}^{2} \sum_{j=0}^{2} \hbar \omega_j |2\rangle\langle j| + \hbar (\omega_j - \Delta_j) |j\rangle\langle j| + \hbar \omega_{\text{cav}} b^\dagger b \]
\[ + \sum_{k\lambda} \hbar \omega_k [a_{k\lambda}^\dagger a_{k\lambda} + a_{k\lambda}^\dagger a_{k\lambda}] \] (27)

the conditional Hamiltonian becomes

\[ H_{\text{cond}} = i\hbar g \sum_i \left[ |e_2 \rangle\langle 1| - \text{H.c.} \right] + \frac{1}{2} \hbar \{ \Omega_{\text{eff}} |2\rangle\langle 1| \}
\]
\[ + \Omega_{20} |2\rangle\langle 0| - \text{H.c.} \right] + \frac{1}{2} \hbar \sum_{i,j} \{ \Omega_{ij} |j\rangle\langle j| + \text{H.c.} \}
\]
\[ + \hbar \sum_{i,j} \Delta_j |j\rangle\langle j| + \text{H.c.} \]
\[ + \frac{i}{2} \hbar \kappa b^\dagger b - \frac{i}{2} \hbar \sum_{i,j} \Gamma_j |j\rangle\langle j| \] (28)

A. The no-photon time evolution

In this section we determine the parameter regime required for the scheme to behave as the two atoms in Fig. 2 by solving the no-photon time evolution of the two six-level atoms inside the cavity. It is shown that the difference of the scheme based on six-level atoms compared to the scheme discussed in Sec. II is that the parameters \(\Omega_0\), \(\Omega_1\), and \(g\) are now replaced by some effective rates \(\Omega_{\text{0 eff}}, \Omega_{\text{1 eff}},\) and \(g_{\text{eff}}\) and one has \(\Gamma = 0\). In addition, level shifts are introduced.

First, we should assume that the detunings \(\Delta_j\) are much larger than all other system parameters. This allows us to eliminate adiabatically the excited states \(|e_j\rangle\). The amplitudes of the wave function of these states change on a very fast time scale, proportional to \(1/\Delta_j\), so that they adapt immediately to the system. We can therefore set the derivative of their amplitude in the Schrödinger equation (13) equal to zero. Neglecting all terms proportional to \(1/\Delta_j\) one can derive the Hamiltonian \(H_{\text{cond}}\), which governs the no-photon time evolution of the remaining slowly varying states. It equals

\[ \tilde{H}_{\text{cond}} = \hbar g_{\text{eff}} \sum_i \left[ |2\rangle\langle 1| - \text{H.c.} \right] + \frac{1}{2} \hbar \{ \Omega_{\text{eff}} |0\rangle\langle 2| \}
\]
\[ + \Omega_{1 \text{ eff}} |1\rangle\langle 2| + \text{H.c.} \}
\]
\[ - \hbar \frac{\Omega_{20}^2}{\Delta_0} \sum_i \{ |2\rangle\langle 2| - \frac{1}{4} \hbar \frac{\Omega_{22}^2}{\Delta_1} |2\rangle\langle 2| \}. \] (29)

The first three terms in this conditional Hamiltonian are the same as the terms in the Hamiltonian \(H_{\text{cond}}\) in Eq. (16) but with the Rabi frequencies \(\Omega_j\) now replaced by

\[ \Omega_{\text{eff}} = \frac{\Omega_{ij}}{2\Delta_j} \] (30)

and the coupling constant \(g\) replaced by the effective coupling constant

\[ g_{\text{eff}} = \frac{g \Omega_{22}}{2\Delta_2} \] (31)

and with \(\Gamma = 0\). The final four terms all represent level shifts. The first one of these introduces a level shift to the states \(|n\rangle\), with \(n > 0\), while the others correspond to a shift of the states \(|0\rangle, |1\rangle,\) and \(|2\rangle\) of each atom.

To use the setup shown in Fig. 6 for the realization of a controlled-NOT gate operation we have to assume in analogy to Eqs. (2) and (3) that

\[ \Omega_{\text{0 eff}} = \Omega_{1 \text{ eff}} \] (32)

and

\[ |\Omega_{\text{0 eff}}| \ll \frac{g_{\text{eff}}^2}{\kappa} \] and \(\kappa\). (33)

By analogy with Eq. (4) the length \(T\) of the weak laser fields with Rabi frequency \(\Omega_{\text{0 eff}}\) should be

\[ T = \frac{2 \pi}{|\Omega_{\text{0 eff}}|} = \frac{4 \pi \Delta_0}{\Omega_{20} \Omega_{00}}. \] (34)

In addition the parameters have to be chosen such that the level shifts in Eq. (29) have no effect on the time evolution of the system. If the shifts are appreciable then significant phase differences accrue in the computational basis, leading to a marked decrease in gate fidelity. They may be neglected if they are negligible compared to the effective Rabi frequencies or the effective coupling constants \(g_{\text{eff}}\) of the corresponding transition. If we choose

\[ \Omega_{20} \ll \Omega_{00}, \quad \Omega_{21} \ll \Omega_{11}, \quad \text{and} \quad g \ll \Omega_{22} \] (35)

then \(g^2/\Delta_2\) becomes negligible compared to \(g_{\text{eff}}\), and \(\Omega_{22}^2/\Delta_0\) and \(\Omega_{22}^2/\Delta_1\) are much smaller than \(\Omega_{\text{0 eff}}\) and \(\Omega_{1 \text{ eff}}\).
The initial state of the qubits in the following is as in Sec. II given by |10⟩.

Figure 7 shows the success rate for a single controlled-NOT gate operation. As one can see by comparing the results for Γ = 0 to the results for Γ = 0 in Fig. 4, the presence of the additional level shifts in Eq. (29) increases slightly the no-photon probability of the scheme. Otherwise, it shows the same qualitative dependence on Γ and Ω₀ or Ω₂₀, respectively, in both figures. The main advantage of the scheme using six-level atoms is that the spontaneous emission rates of the excited states |e⟩ can now be of the same order as the cavity coupling constant g without decreasing the success rate of the gate operation significantly, which allows for the implementation of the scheme with optical cavities.

The no-photon time evolution of the system over a time interval T indeed plays the role of a controlled-NOT gate to a very good approximation. The quality of the gate can be characterized through the fidelity F defined in Eq. (15). The fidelity obtained through numerical solution is now very close to unity. For the whole range of parameters used in Fig. 7 it is above 99.8%.

One could object that the duration T of the gate presented here is much longer than for the gate described in the preceding section. But, as predicted in Sec. II B, the ratio of the gate-operation time to the decoherence time is highly reduced. One of the main requirements for quantum computers to work fault tolerantly is for this ratio to be low. This is now fulfilled for a much wider range of parameters.

IV. CONCLUSIONS

We have shown in this paper that it is possible to fulfill all the requirements placed upon a universal quantum computer in a quantum-optical regime. We have presented two such schemes, the first is similar to that shown in [20] except that it has been optimized for simplicity and its construction is feasible using current experimental techniques. The second suggestion builds on this by substantially reducing the errors arising from spontaneous decay at the expense of slightly increased complexity of implementation.

By comparing the underlying physical mechanism to that observed in electron-shelving experiments, we hope to have shed new light on passive methods of coherence control.

As a first step to test the proposed scheme one could use it to prepare two atoms in a maximally entangled state and measure its violation of Bell’s inequality as described in [51]. Finally we want to point out that we think that the idea underlying our scheme can be carried over to other systems and to arbitrary forms of interactions to manipulate their state and so lead to a realm of new possibilities for the realization of decoherence-free quantum computing.
